Director, Department of Experimental Surgery, McGill University
Surgeon in Chief, Royal Victoria Hospital
Injuries Due to Physical Agents, Stomach and Small Intestine

E. WALTER WORKMAN, M.D., C.M., M.Sc., F.A.C.S.

Lecturer in Anatomy, McGill University
Assistant in the Outdoor Clinic, Royal Victoria Hospital
Evolution of Modern Surgery

Preface to Third Edition

The completion of the materials for this third edition is significant, as the coverage and content approximate for the first time that intended when the project was originally planned in 1945. We have profited greatly from the constructive suggestions obtained during the past year in response to a questionnaire sent to teachers in all medical schools of Canada and the United States. Their comments, together with those of numerous teachers and students at home and abroad, have helped to establish the underlying editorial policy which is reflected in this new volume. For all such assistance the editor wishes to express his sincere gratitude.

The reader and reviewer will note that the materials have been completely revised, expanded, and brought up to date. In addition, an important new chapter on Pediatric Surgery, written by Dr. Gordon M. Karn and Dr. Harvey E. Beardmore of The Montreal Children's Hospital, has been included in this edition. This indicates a departure from past policy which tended to restrict the contributors to the staff of the Royal Victoria Hospital and certain allied departments of McGill University, whereas the editor's original plan was to make this textbook representative of the teaching and practice of the three hospitals associated with the surgical staff of McGill University.

Since the most rapid changes have occurred in the surgery of the heart, great vessels, and lungs, these sections have been completely rewritten and extended. Dr. Arthur M. Vineberg and Dr. David R. Murphy have contributed the new chapter on Cardiac Surgery, and in this section valuable assistance has been given by Dr. A. Dobell and Dr. G. D. Hooper. Dr. Darrell D. Munro collaborated in extending and revising the chapter on Thoracic Surgery.

Additional new contributors are Dr. Lloyd G. Stevenson, who assisted in the chapter on Evolution of Modern Surgery; Dr. Gardner C. McMillan, who has rewritten the chapter on Inflammation and Repair; Dr. Roger W. Reed, who has joined Dr. Gertrude G. Kalz in bringing the chapter on Surgical Bacteriology and Chemotherapy up to date; Dr. Alan B. Noble and Dr. Philip R. Bromage, who have collaborated with Dr. Richard G. B. Gilbert in the chapter on Anesthesia; Dr. William R. Foote, who has worked with Dr. George A. Sumpson on the enlarged chapter on the Female Genital Tract, which replaces the restricted coverage of the Abdominal Aspects of Gynecology in the first two editions, and Dr. Martin A. Entin, who has written the section on Open Wounds and Soft Tissue Injuries of the Hand that is included in the editor's chapter on Fractures and Disorders of the Upper Extremity. Dr. Edward J. Tabah has extended his coverage of Diseases of the Face, Mouth, and Neck and has assisted Dr. Munro and the editor with the enlarged chapter on the Esophagus.

In compliance with repeated requests, the editor has extended the coverage of the ankle and foot to correspond with that for the hip and knee and, for this, twenty-one additional color plates have been included. Five further color plates bearing on the surgery of the great vessels will be found in Dr. Josephus C. Luke's section with the kind permission of Dr. M. E. DeBakey. Four additional color plates are included in the chapters on the Liver, Biliary System, and Female Genital Tract. In all, there are thirty

PREFACE TO THIRD EDITION

additional plates, making a total of 108 color plates in this new edition. One hundred sixty-eight additional black and white photographs and drawings have been added to maintain the profusion of visual aids which has been an essential feature of this textbook

The editor wishes to take this opportunity to thank all the contributors for their part in the production of this volume. Our gratitude also extends to Ciba Pharmaceutical Products, Inc., for their continued support which has lightened the editor's burden in each edition. Further acknowledgment is given to Miss Olive Hosmer, who not only has made a generous gift to assist this edition but has also recently endowed the Department of Medical Illustration at the Royal Victoria Hospital. This is significant in that the Department was founded in order to illustrate the first edition of the *Textbook of Surgery* and has functioned since that time as the center from which further editions have been produced

The greatest credit must go to Miss Helen MacArthur, our medical illustrator, who has assisted the editor and contributors in every phase of this major academic endeavor. Mrs. Max Slapack has been responsible for the preparation of the manuscript, Mr. Harold Coletta for the photography, and Mrs. F. D. Peart for the checking of many of the references

Since the second edition was published we have lost our valued friend, Miss Marguerite Stadelhofer, of The C. V. Mosby Company, with whom we worked so happily on the first two editions, and we hereby acknowledge the valuable assistance she has given us

Montreal

H. FRID MOSBY

Preface to First Edition

The writing of a textbook to contain the principles of surgery and the amount of factual information required by students at the time of their graduation and during their early period as interns was proposed by me in this center several years ago.

In order better to understand the approach to be followed, student forums were held. These indicated that the students, following the present trends in visual education, wished a profusely illustrated volume. They asked that sections on the Eye, Ear, Nose and Throat, and on Gynecology, apart from that required in the differential diagnosis in abdominal conditions, be omitted, since separate texts were used in these subjects. It was also decided that anatomy, physiology, and pathology should be integrated in the text and that no attempt be made to cover in detail these fields, since they are more adequately dealt with in their respective books.

To ensure the integration of the materials, the sections have been written by members of the Surgical Department of the Royal Victoria Hospital and of the Departments of Neurosurgery, Obstetrics and Gynecology, and Pathology, all associated with McGill University. Great overlap and cooperative discussion were required to achieve this end. Many difficulties presented from the rapid specialization even within special fields and the recent great changes due to chemotherapy, anticoagulants, and improved surgical technique. Balancing the proportions of various sections has been a great problem, and it is hoped that further critical evaluation will assist in this respect.

A book of this type represents the collective support of many individuals, and on behalf of the contributors I would like to acknowledge our debt to Dr. G. Gavin Miller, our Surgeon-in-Chief, who has placed the facilities of his Department at our disposal, to Drs. J. C. Armour, A. L. Wilkie and C. A. MacIntosh, Senior Consultants in General Surgery, to Dr. Newell Philpott, Director of the Montreal Maternity Hospital; to Dr. Wilder Penfield, Director of the Montreal Neurological Institute; to Dr. Emerson Smith, Urologist-in-Chief; to Dr. F. A. H. Wilkinson, Anesthetist-in-Chief, to Drs. Carleton Peirce and E. C. Brooks, Senior Radiologists of the Royal Victoria Hospital, and to Dr. Lyman Duff, Director of the Pathological Institute, all of whom have given valuable advice and criticism in the respective sections. We are also indebted to Dr. J. C. Meakins and Dr. E. H. Mason of the Department of Medicine for assistance on medical problems.

The photographic work is largely the product of Harold Coletta of the Pathological Institute. The references have been checked by Mrs. F. D. Peart of the Medical Library. The manuscript has been meticulously prepared by Mrs. Max Slapack.

Great credit is due to Miss Helen MacArthur of the Department of Medical Illustration of this Hospital, who, during the past three and one-half years, has worked assiduously to prepare the illustrations for this textbook and who has also assisted greatly in its organization and integration.

The editor wishes to thank all his colleagues who have given up their leisure time to write their individual sections and to contribute to the correlation of the materials. It is our hope that this textbook will assist students at all stages in their investigation of the fascinating study of surgery.

Chapter 1

Evolution of Modern Surgery

E. Walter Workman, MD, Lloyd G. Stevenson, MD,
and H. Fred Moseley, DM.

The practice of surgery, growing more scientific and more successful year by year, has undergone many changes during the last century, following a very long period in which it was essentially a traditional craft, slow to alter. The surgeon, although his skills slowly improved and his social and professional status rose, was in many ways a stock figure, recognizably the same in the 17th century as in antiquity. Some of the characteristics of this relatively unchanging surgeon of old could still be discerned in his modern counterpart of the early 20th century.

THE "OUTSIDE DOCTOR"

The distinction between physician and surgeon was not well marked in the Hippocratic era; nevertheless, the decrying of all manual endeavor as vulgar and low, a form of snobbery peculiarly Greek, was one of the reasons for the subsequent lowly status of the surgeon. In afterages and during many centuries of Western European history, the surgeon was a mere artisan, a common mechanic who had little association with the learned professions, of which medicine was one. Much the inferior in education of the higher-ranking physician, he became, in two senses, the "outside doctor." Doctor he was not, if the word is taken to mean a learned teacher, but doctor he certainly was in the modern popular sense of one who ministers to the sick and injured; and standing as he did for so long outside the regular profession of physic, he was also the

"outside doctor" in having only the outside of the patient—the wounds, the outward herniations, the diseased eyes, the hemorrhoids, the ulcers and the other skin lesions—as his special province.

It is not surprising, in view of the old distinction between surgery and physic, or "internal medicine," that dermatology and syphilology once formed a branch of surgery rather than one of the medical specialties. Jonathan Hutchinson, who lived until 1913 and who is best remembered for his contributions to our knowledge of syphilis, was a surgeon-dermatologist. So was Francis J. Shepherd, Osler's contemporary and friend, who used to teach anatomy at McGill University in the winter and operate at the Montreal General Hospital in the summer. He was Montreal's first dermatologist.

MEDICINE AND SURGERY

The historical relationship between medicine and surgery, a subject of great interest and value, has been investigated by Sir Clifford Allbutt and more recently by Owsei Temkin. According to Temkin, the advances of surgery played a significant part in the rise of modern medical thought. For centuries surgery depended upon an objective anatomic diagnosis; it was not until the 18th century, however, that medicine adopted the surgeon's outlook of a localized pathology in the diagnosis and treatment of disease.

EVOLUTION OF MODERN SURGERY

PRACTICE AND THEORY

Before the 18th century the practicing surgeon was almost invariably an ignorant man of the people and it was only very gradually that the picture changed. True, the famous surgeons of the long robe in 14th century France were in some measure exceptions to the rule, but most surgeons everywhere were ill-educated for another 400 years at least. Men there were, in all parts of Europe, who knew a great deal about surgery in theory who never touched a knife. In the 18th century we find Albrecht von Haller lecturing on surgery at Göttingen University and bringing a vast bibliography of surgical writings, still a useful reference, but never practicing. All of his surgical knowledge, great practical anatomist and physiologist though he was, was merely book learning. A practical literature did indeed exist, but it was based on ancient sources and was unendingly repetitious. Only about this time was it beginning to reach out toward science.

As for the practicing surgeon, innocent of Latin and not dependent on books, he had learned the techniques of his craft as an apprentice, like his master before him. For this reason we can seldom be sure that the first account of any operation in the older literature was not preceded by a long unwritten history. Who invented the method of treating fracture of the clavicle with a sandbag between the shoulder blades as described in the Edwin Smith Papyrus of 1700 B.C.? We are reasonably sure that much of the other knowledge preserved in this venerable work is older by centuries than the presumed date of the document itself. Throughout antiquity technical information was largely in the public domain; nobody was much concerned about the "secrets." Operative treatment for hernia, bladder stone, and cataract is of very ancient date. Several centuries before the birth of Christ, the treatment of fractures and dislocations had already reached an advanced stage of development among the Hippocratic surgeons of Greece. We know that the plastic surgery of the Renaissance, as set forth by Gasparo Tagliacozzi, was the outgrowth of traditional practice, often carried on by successive members of the same family.

The practicing surgeon languished for centuries outside the pale of the regular profession. In London he belonged, from the 16th century, to the same guild as the barbers and not until nearly the middle of the 18th century did the Surgeons' Company establish itself as a separate entity. This should not be taken to mean that barbers and surgeons were identical. Even in the 16th century London guild, barbers took no part in the examination of surgeons. Nevertheless real barber-surgeons carried on their dual business everywhere in Europe. The surgeons in the armies of Frederick the Great were required to shave the officers, and as about the time when the London surgeons were setting up the Surgeons' Company, Frederick gave permission to Prussian executioners to treat fractures, wounds and ulcers, to the great indignation of his surgeons.

THE BASIS OF MODERN SURGERY

When practical men were ignorant and learned men were pedantic and antiquarian, progress was slow. English medical education escaped from the grip of scholasticism in the London hospitals, where surgery gradually came into its own. Oxford and Cambridge even more firmly rooted in scholastic tradition than the universities of the Continent, were remote from clinical experience. In 18th century Edinburgh, the university and hospital could be happily wedded, partly because they existed side by side in the same urban center.

It was in the universities of Italy, however, rather than in the hospitals, that the groundwork had been laid for modern surgery by the anatomic investigations of Andreas Vesalius and some of his contemporaries of the 16th century. The year 1543 had seen the publication of the first modern anatomic text, the *De Humani Corporis Fabrica* of Vesalius. Professor in the University of Padua. Two centuries later, when pathology began to rival normal human anatomy as the basic discipline of the surgeon, the hospitals, whether linked with universities or not, made the chief contribution. Physiology, on the other hand, coming to the aid of surgery in still more recent times, has grown up in a university setting. University and hospital, with the disciplines peculiar to each, have flourished best when in close association with each other.

The rise of modern anatomy was the first preliminary to the development of modern surgery. It replaced the long-venerated teachings of Galen, a Greek doctor who worked in Rome in the 2nd century of our era. Galen was an expert anatomist but unfortunately had little opportunity to work with human materials and had to be content with apes, oxen, and other animals. His skill in experimental physiology proved harder to match.

SCIENCE AND PRACTICE

While surgery may be said to have waited on the growth of the sciences which nourish it, surgeons did not, and could not wait, their work continued, and not without improvement. Even in the early Middle Ages, the "Arabians"—all those who wrote in Arabic—were responsible not only for transmitting the knowledge of antiquity but for adding to it, especially in pharmacology and ophthalmology. By the 13th century the names of Theodoric and Henri de Mondeville remind us that the non-suppurative treatment of wounds was attempted very early. The concept of "healing by first intention" is, however, a Galenic concept, a fact to remember when we read that Galen believed pus to be necessary for the healing process. John of Arderne, in the 14th century, perfected an early technique for operating on *fistula-in-ano*. In surgery, as in other crafts, our medieval forbears did not lack in ingenuity, and some part, at least, of the glory of the Renaissance is literary artefact.

Renaissance surgery, fortified by the "new anatomy," nevertheless continued to progress on the old practical lines. Good things lost from sight had to be brought back. Ambroise Paré re-introduced and popularized (he did not invent) the use of the ligature to control hemorrhage. Like other great surgeons, he made constant use of the experience of daily practice. His adventurous, controlled experiment in treating some patients with gunshot wounds with boiling oil, at that time the standard procedure, and others with a bland ointment taught him that such wounds are not "poisoned" by gunpowder and not helped by cauterization. Paré is the supreme example, among many others, of the innovating military

surgeon. His contemporary, Pierre Franco, was probably the first to attempt the surgical treatment of strangulated hernia.

The 17th century carried forward the same means of advance. Knowledge of anatomy was of benefit in the treatment of fractures, in the emergencies of hemorrhage, and in various other ways, but for more than two centuries longer, surgical procedures were still to be very much limited by the necessity for speed, so that fancy disarticulations and so forth were not of much practical importance, though the state of anatomy permitted such undertakings. Seventeenth and many 18th century surgical texts, despite all improvements, still manifestly belong to the era of the old surgery. Amputation remained too often the first and not the last of the surgeon's resources.

Still, observation and ingenuity counted for much. In 1752 Jacques Daviel substituted cataract extraction for the age-old operation of couching, or downward dislocation of the cataractous lens on the end of a needle. Like many innovations this was the result of a happy accident in practice, seized upon and followed up by a keen practitioner. At the same time surgery was drawing more and more upon experimental science, John Hunter, a great 18th-century Scot practicing surgery in London, seems to have learned from purely scientific experiments on deer how rapidly collateral circulation, already known, may take over the function of the main artery of a part, and this knowledge he applied in devising a new and successful operation for popliteal aneurysm. Comparative anatomy he employed as another approach to physiology. He was likewise a good pathologist. In the 17th century, and increasingly in the 18th century, surgery began to be more than an empirical craft. Simultaneously the great hospital schools were developing and the surgeon was rising in social status and professional esprit.

The great surgeons of the late 18th and early 19th centuries, like Astley Cooper and James Syme, were primarily concerned with applied anatomy. Astley Cooper contributed not only by his great works on fractures and dislocations and on diseases of the breast, but also by his contributions to vascular surgery. He was the first to ligate the aorta successfully. James Syme

will be remembered for his resections of the capula, the forequarter, the lower jaw, and the major joints, as well as for the amputation that bears his name Jacques Lisfranc was in many ways the French counterpart of Syme. But pathology, too, played its part. Dupuytren, for example, was a first-class surgical pathologist. Karl Ferdinand von Gräfe in Germany and Philibert Roux in France extended the domain of plastic surgery. Orthopedics and ophthalmology progressed. Gynecologic surgery made a fresh beginning in America with Ephraim McDowell's ovariectomy and the pair of vesicovaginal fistula by Marion Sims. But surgeons of every sort pulled up helplessly in the face of the two problems of greatest significance to all—pain and sepsis.

ANESTHESIA

The introduction and development of anesthesia preceded antiseptics and asepsis. By 1850 anesthesia was in general use. Although ether had been known since the 16th century, it was first used in surgical practice on March 30, 1842, by Crawford Williamson Long, who did not publish his results at the time of his case. However, ether did not become popular until October 16, 1846, when W. T. G. Morton, a dentist, successfully demonstrated the use of ether on a patient of John Collins Warren at the Massachusetts General Hospital. In 1847 chloroform (discovered in 1831) was first used by Sir James Y. Simpson on obstetric cases. It soon became the usual anesthetic in Great Britain. Chloroform has been utilized more than ether in Europe, while the reverse is true in America. Nitrous oxide was isolated in 1776 by Joseph Priestley. Humphry Davy noted the effect of the gas when inhaled, he suggested its use during surgical operations but never attempted to employ it. Horace Wells, a dentist, administered nitrous oxide while extracting teeth in 1844. One of Wells' patients died during nitrous oxide administration after which he gave up his researches and the practice of dentistry. Nitrous oxide became a safe anesthetic when Edmund W. Andrews in 1868 introduced a mixture of oxygen with the gas. Ethylene, discovered in the 17th century, did not come into use until introduced by Luck-

hardt and Bailey in 1923. Although this agent approached the ideal anesthetic since it was fast acting and caused minimal disturbance of carbohydrate metabolism, ethylene did not continue to be popular because it was highly explosive and did not induce adequate relaxation. Cyclopropane discovered by August von Freund in 1882, studied as an anesthetic by G. H. W. Lucas and V. E. Henderson in the 1920's, was first administered clinically in 1930 by Ralph M. Waters and his associates. This agent proved to be a great advance because in addition to the advantages of ethylene it produces a greater degree of muscular relaxation and permits the use of a high percentage of oxygen. It is, however, explosive and has a tendency to produce ventricular fibrillation. While the development of intravenous anesthesia commenced with the synthesis of the barbiturates in 1904, the introduction of hexobarbital (Evinpan) in 1932 and thiopental sodium (Pentothal sodium) two years later established this form of anesthesia. Intravenous thiopental sodium has now come into general use for minor surgical procedures and in combination with other types of anesthesia. The use of local anesthesia came after antiseptics and asepsis. In 1883 cocaine was used to abolish pain in eye operations. Halsted was the pioneer in local cocaine infiltration anesthesia, and in 1885 his work was well established. With the discovery of novocaine by Einhorn and its clinical use by Braun in 1905, local anesthesia came into general use. Although August Bier developed and popularized spinal anesthesia in 1893, the first spinal anesthesia in man was performed in 1883 by James Leonard Corning. There have been further developments with the introduction of epidural anesthesia (1920), continuous spinal anesthesia (1940), and, more recently, catheter spinal anesthesia.

Muscular relaxants were brought into anesthesia in 1942 with the introduction of curare by H. R. Griffith and G. E. Johnson. This drug was used for centuries by the Orinoco Indians of South America as their arrow poison.

Recent physiologic studies of the anesthetics have led to their more selective application and to their use in combination to obtain the optimum result.

Fig 1—Lord Lister (1827-1912)

THE LISTERIAN ERA

In 1864 Pasteur proved that fermentation depended upon living organisms and thus began the conquest of sepsis and the era of modern surgery. In 1867 Joseph Lister published his paper on "The Antiseptic Principle in the Practice of Surgery." He laid the foundation for *asepsis* and *antiseptis*. In 1871 he introduced the carbolic spray which was in use until 1887. The purpose of the spray was to kill germs in the air. In 1880 he introduced the absorbable catgut ligature. The science of bacteriology was advanced by Robert Koch when in 1878 he showed that each type of wound infection was due to a specific organism. This placed surgery upon a firm scientific basis. The antiseptis of Lister was replaced by aseptic methods when Bergmann in 1886 introduced sterilization by boiling and Halsted in 1891 introduced the use of rubber gloves for operations. Asepsis made possible the extraordinary development of abdominal surgery at the end of the 19th century as exemplified by Billroth.

X-RAYS

Direct examination of the body cavities by endoscopic means was in use before the advent of x-rays. Methods of intubation of the larynx

were known since the time of Hippocrates and preceded the direct examination of it. At about the middle of the 19th century the laryngoscope became a popular instrument and laryngoscopy was established as a procedure for diagnosis and treatment. The introduction of the cystoscope in 1879 initiated rapid progress in endoscopic techniques for other parts of the body.

Following anesthesia, antiseptis, and asepsis came the discovery of x-rays in 1895 by Wilhelm Konrad Röntgen. After this event there was rapid development and 10 years later the specialty of radiology was established. X-rays were first used to visualize foreign bodies and, later, fractures. Advances in methods of diagnostic radiology came with the development of procedures using radiopaque media. The first of these was utilized by Walter D. Cannon when he gave a radiopaque meal of bismuth subnitrate to visualize the gastrointestinal tract. Later barium sulfate was generally adopted for this purpose. In 1924 Graham and Cole reported their development of cholecystography, using tetrabromphenolphthalein intravenously. This was an event of far-reaching importance in the study of biliary tract and gall bladder disease. Since that time compounds for oral use have been perfected. Recently a substance, Cholografin, has been developed for intravenous use that is especially valuable for studies of the biliary tract after cholecystectomy. The historic considerations of the radiologic visualization of the urinary tract are described with the development of urology. Other advances in the use of contrast techniques have been the introduction of ventriculography in 1918 by Walter E. Dandy and the development of cerebral angiography in 1931 by Egas Moniz and Almeida Lima. More active interest in vascular visualization came in 1937 when Robb and Steinberg reported the injection of large quantities of radiopaque material for visualization of the chambers of the heart and the pulmonary circulation. Aortography and visualization of the peripheral vascular system have now come into general use. Thus by the use of contrast media the scope of radiologic diagnosis has been extended and offers possibilities for continued development.

The field of radiotherapy began when the x-rays were discovered in 1895 and when Henri Becquerel in 1896 found that uranium salts

3 radiations Early in the history of radiology the x-rays were used therapeutically for skin malignancies, skin diseases, leukemia, and lymphadenoma The invention of the mechanical rectifier by Clyde Snook in 1905 initiated the production of higher voltage apparatus At that advance was made when the hot cathode filament tube was developed by W. D. Coolidge in 1913 This Coolidge tube, although modified, is still standard in principle A super-voltage x-ray generator, having a capacity of 1,000,000 volts, was built in 1935 by R. A. Rife and his associates An evaluation of this form of therapy indicated that it is a refinement rather than a great improvement In 1941 the betatron developed by Kerst generated 20,000,000 electron volts This apparatus has been used successfully in the treatment of cancer

Radium was discovered in 1898 by Pierre and Marie Curie and is still used today, although more in Europe than in North America Radium in conjunction with x-rays is used in the treatment of cancer of the cervix

The era of artificial radioactive materials commenced when Ernest Orlando Lawrence constructed the cyclotron in 1932 In 1942 Fermi was the first to build a nuclear reactor for the production of isotopes Isotopes have been used for tracer studies and the treatment of cancer Cobalt⁶⁰ is now used extensively in the form of cobalt bomb as a means of teletherapy and in needles and tubes for interstitial and intracavity therapy

While radiotherapy alone has been curative and palliative in the treatment of cancers, it has often been used in conjunction with surgery The therapeutic effect of radiation depends, in addition to other factors, upon the radiosensitivity of the lesion

Thus by the end of the 19th century the three great pillars were placed and modern surgery was established

SURGERY IN THE TWENTIETH CENTURY

The 20th century may be divided into two periods, 1900-1936 and 1936 until the present The first period was influenced by World War I and the discovery of insulin The second period was influenced by World War II and

Fig. 2 - Sir Frederick Banting (1891-1911)

the advent of the *sulfonamides* and the *antibiotics*

As a result of World War I, antiseptics, germicidal but less destructive to tissues, were developed Débridement of wounds and prophylactic inoculation against tetanus were introduced In 1921 Banting, Best, Macleod, and Collip discovered insulin This discovery had a profound influence on the surgical treatment of diabetes Diabetic gangrene was more easily controlled and operations on the diabetic could be performed with the same degree of safety as on the nondiabetic

The Age of Chemotherapy and the Antibiotics

The age of chemotherapy had its inception in 1906 when Paul Ehrlich discovered Salvarsan, but it was not until 1936 that the sulfonamides came into use for the treatment of infections With this the present era was ushered in Gelmo in 1908 synthesized para-aminobenzenesulfonamide (sulfanilamide) which was used in the dye industry It was not until 1933 that Foerster in Germany reported upon the first clinical use of a sulfonamide compound known as Prontosil Dornag

in 1935 reported the first experimental work on Prontosil in which he proved that it prevented fatal hemolytic streptococcal infections in mice. Simultaneously there appeared clinical confirmation of Domagk's work in that the drug was effective in septic hemolytic streptococcal angina, erysipelas, puerperal sepsis, and other infections. In 1936 Colebrook and Kenny in England reported that Prontosil and a variant Prontosil S were of definite value in the treatment of puerperal sepsis. Interest in these compounds in the United States did not appear until 1936 when investigations were begun by Mellon and his associates, Rosenthal and Bauer, and Long and Bliss. Long and Bliss formed the hypothesis that sulfanilamide acted directly upon the invading microorganism and that this action was primarily one of bacteriostasis. They were convinced that Prontosil, Prontosil S, and sulfanilamide were of definite therapeutic value in streptococcal infections.

During the years of World War II there followed sulfapyridine in 1939, sulfathiazole in 1940, sulfadiazine in 1941, and sulfamerazine in 1943. Then followed Sulfasuxidine and Sulfathalidine. New sulfonamide compounds are continually being developed.

Fig. 3—Sir Alexander Fleming (1881-1955)

In 1929 Alexander Fleming discovered *penicillin* and suggested that it might be an effective bacteriostatic agent to penicillin-sensitive organisms. Fleming's discovery remained unnoticed until 1940 when interest in the clinical use of penicillin was aroused following the investigations of Chain, Florey, and their associates at Oxford University. Since that time, the other antibiotics, including *streptomycin*, *Aureomycin*, *chloramphenicol*, *erythromycin*, and *tetracycline* were discovered. New antibiotics are constantly being produced. From 1940 there has been greater progress in the control of infections than has taken place in all previous medical history. The use of the sulfonamides and the antibiotics has made practical many surgical procedures that before were not possible with any degree of success.

The Control of Blood Coagulation

The anticoagulants *heparin* and *Dicumarol* have been two extremely effective agents of therapy for venous thromboembolic disease. As late as 1934 surgery was helpless against thrombosis. Heparin was discovered by McLean in 1916. In 1933 Best and his co-workers solved the problem of preparing large quantities of heparin. Between 1935 and 1942, Gordon Murray in Canada and Crafoord in Sweden simultaneously and independently showed that thrombosis can be prevented by heparin post-operatively. Dicumarol was described, isolated, and synthesized by Link in 1940 and came into clinical use in 1941. It is interesting that the discovery of this agent was due to Schofield, who in 1922, in the *Canadian Veterinary Record*, described a disease of cattle in which there was a tendency to bleed after eating spoiled sweet clover. The use of the anticoagulants after major surgical procedures for prophylaxis and treatment has diminished the incidence and mortality of pulmonary thrombosis and embolism. With these two agents greater safety in vascular and cardiac surgery became possible. A method of increasing the coagulability of the blood and the prevention of post-operative hemorrhages in obstructive jaundice became available with the advent of *vitamin K* ("Koagulations-Vitamin"). This was discovered by Dam in 1934 and was used clinically in 1938.

Blood Transfusions

Although blood transfusion had its inception in the 17th century, further investigation of its possibilities awaited the turn of the present century. Blood transfusion was successfully performed on dogs by Richard Lower in England (1666). Because of the lack of knowledge of iso-agglutinins and the many consequent failures in human beings, it was forbidden and abandoned for approximately 150 years. With the introduction of blood grouping in 1900 by Landsteiner and independently by Shattock the modern era of blood transfusion began. World War I saw the introduction of the citrate method which allowed blood to be stored for a few days before use. After the successful use of cadaver blood in 1927 by W. N. Sharnov, Kostinkov, and S. S. Yudin of Russia, there followed the development of banks of preserved blood and plasma. Refined methods of blood grouping, matching, and storing are now in general use and better methods of combating shock have thus been developed.

SURGICAL SPECIALTIES

In the first half of the 20th century there have been such tremendous advances in surgical knowledge that increased specialization in the various branches was necessitated. Each of these surgical specialties in turn has become highly developed and technical. A brief consideration of their evolution and status may contribute to a picture of present-day surgery.

Abdominal Surgery

Abdominal surgery has developed rapidly since the beginning of this century. At that time the aseptic method of opening the peritoneal cavity was introduced and appendectomy had become a frequent operation. Gastroenterostomy, first performed by Wölfler in 1881, reached the height of its popularity in the late 1920's for the surgical treatment of peptic ulcer. This was later replaced by subtotal gastrectomy as the operation of choice. The first successful partial gastrectomy was performed for cancer of the pyloric region by Theodor Billroth on January 29, 1881. The Billroth I operation included an anastomosis of the cut end of the stomach to the cut end of the duodenum. In 1884 he introduced the Billroth II

operation in which he anastomosed the posterior surface of the stomach to the cut end of jejunum. This operation, modified by von Eiselsberg, Polya, Hofmeister, Finsterer, Moynihan, Balfour, and others, is the surgical procedure now most frequently used. In 1943 Dragstedt and Owens, advancing Pieri and Tanfagna's technique, began to perform vagotomy for duodenal ulcer. Later they combined this operation with gastroenterostomy which proved to be of value in certain cases. Vagotomy alone has been used effectively for gastrojejunal ulcer after gastric resection and for early cases of ulcerative colitis. Progress has been made in the differentiation of gastric ulcer and gastric carcinoma. In addition to x-ray procedures there has been the development of gastroscopy by Schindler and others, exfoliative cytologic techniques, and electrogastrography.

In 1826 Antoine Lembert described his method of intestinal suture and laid the foundation of modern intestinal surgery. The anastomosis button devised by J. B. Murphy in 1892 was used successfully in gastroenterostomies but did not reduce the high mortality rate of primary colonic resection. As a result, a safer procedure, the exteriorization resection of bowel, was developed by Oscar Block (1892) and Paul (1895) and popularized by Mikulicz in 1903. The aseptic anastomosis introduced by Parker and Kerr in 1908 was only later accepted. The sulfa drugs and then antibiotic agents have made the operation of resection and primary anastomosis the procedure of choice. The control of infection has also allowed extensive one-stage large bowel surgery.

Marked advances have been made in the treatment of intestinal obstruction through the studies of Dragstedt (1917), Haden and Orr (1923), Gamble and Ross (1925), and others. In 1933 Wangenstein popularized intestinal decompression by suction; this has been modified by Miller, Abbott, and others and has proved epoch-making in abdominal surgery. Following investigations of the physiology and chemistry of intestinal obstruction, the prime importance of adequate fluid and electrolytic balance has been recognized. In 1908 Ernest Miles introduced the abdominoperineal resection for carcinoma of the rectum which, in principle, is still most widely used, despite the development of many other operations.

While resections of portions of the liver were done at the end of the last century, there were no further reports until 1921 when Peck performed a left lobectomy for an angioma. Since then this operation has been successfully used for primary neoplasms. It was not until 1919 that Wangenstein successfully removed the entire right lobe of the liver, which operation has since been repeated by others.

In biliary tract surgery since about 1921 cholecystectomy has replaced cholecystostomy. Commencing in 1924 more exact methods of biliary diagnosis have been developed and are described elsewhere. Liver damage has been extensively studied and methods of therapy have been discovered. Vitamin K was introduced in the preoperative preparation of the jaundiced patient. New techniques for repair of traumatic rupture of the common bile duct have been developed by Walters, Cole, Lahey, and Cattell. In surgery of the pancreas, the first pancreaticoduodenectomy was reported by Whipple, Parsons, and Mullins in 1935. Many procedures have been devised, including total pancreatectomy, but despite the reports of longer survivals the treatment of carcinoma of the pancreas is still unsatisfactory.

In splenic surgery, while trauma is the most common indication for splenectomy, hematologic studies have added many other indications. The treatment of portal hypertension was first devised in 1943 by Whipple, who used a shunt between a major portal tributary and a systemic vein. This form of surgical treatment has been advanced and modified by many others.

Gynecology

Operative gynecology was founded by Abraham McDowell, who performed the first ovariotomy in 1809. This stimulated other surgeons to perfect the technique of this operation, and in the 1850's, mainly through the efforts of

one for vesicovaginal fistula removed that condition from the list of incurable maladies. This achievement was made possible by using the Trendelenburg position, by the invention of the Beck-billed speculum (Sims' speculum) and

silver wire sutures, and by utilizing the retention urethral catheter.

During this century the field of gynecology has grown enormously. To the specialty has been added radiation therapy, endocrinology, and psychosomatic medicine. The type of operation has changed markedly. Whereas suspension of the uterus was once a frequent operation it is now advised only when the indications are clear cut. Fewer radical operations are now carried out for fibroid tumors. Vaginal plastic operations are gradually being replaced by vaginal hysterectomy and repair. Total hysterectomy has replaced supravaginal hysterectomy. While the repair of vesicovaginal fistula has been solved, the etiologic factors have changed—fewer fistulas follow obstetric difficulties and more are due to injury of the bladder during uterine operations and as a result of radiation. The management of sterility, together with the surgical means of studying this problem, is a new development. The importance of endocrinology to the gynecologist is great; e.g., the identification of endocrine tumors has changed the classification of ovarian tumors.

Endometriosis was first described by John A. Sampson in 1921 and is now well understood. One of the great advances in treatment is that the chocolate cyst in the ovary can be "shelled out" and the ovary saved. Radical surgery and radiation therapy in the treatment of cancer of the female pelvis have yielded improved results but the problem still remains unsolved.

Urology

The introduction of the cystoscope in 1877-1878 by Max Nitze inaugurated the era of cystoscopy, and urology as a specialty evolved. Since that time the Brown-Buerger cystoscope, presented in 1909, has with modifications proved to be the most adaptable and popular instrument.

Retrograde pyelography was initiated in 1906 by Voelcker and von Lichtenberg when they used colloidal silver to visualize the bladder and unexpectedly also saw the ureter and renal pelvis. Using sodium iodide, Rowntree in 1923 introduced intravenous pyelography. This method has been perfected and is now a routine procedure. Other diagnostic procedures include perirenal insufflation of oxygen, introduced in

1921 for the diagnosis of adrenal tumors; this has been replaced by presacral insufflation. Renal aortography was utilized in 1929 for the diagnosis of renal cysts and tumors. There have been great changes in therapy. The management of renal tuberculosis has been greatly improved by the use of antituberculous drugs in association with nephrectomy.

Among the advancements in bladder surgery has been the construction of substitute bladders. In 1930 Gilchrist and his associates devised an operation utilizing the cecum and ascending colon. Bricker introduced another method in which an isolated loop of terminal ileum is used as an ileal bladder. These methods offer promising possibilities.

The outstanding contributor to prostatic surgery since 1900 has been Hugh Young, who perfected the "punch" operation and developed the perineal operation and radical procedures for prostatic carcinoma. In addition to the development of the perineal, suprapubic, and retropubic methods of prostatectomy, there has been great interest in transurethral resection, which for practical purposes dates from 1909 when Young introduced the urethrosopic prostatic excisor. There have been many modifications in the 1920's, and with the development of the Stern-McCarthy visual electrotome, great interest was aroused and many improvements followed. This is now a well-established form of treatment for certain prostatic cases. A new approach to the treatment of prostatic cancer was introduced in 1939 by Huggins' work on the endocrine features; this resulted in the use of bilateral orchiectomy for inoperable prostatic carcinoma. Recently Huggins has been studying the relationship of the pituitary and adrenal to this condition.

Thoracic Surgery

The foundation for modern thoracic surgery was laid, with attempts to control pneumothorax in open operations of the chest, by Ferdinand Sauerbruch with his negative pressure cabinet and Willy Meyer with a positive pressure apparatus. Sauerbruch's cabinet, introduced in 1903, weighed 10,000 pounds and necessitated that the patient and the operators be inside the enclosure with their heads outside. The problem was solved in 1909, when

S. J. Meltzer and J. Auer introduced positive pressure endotracheal anesthesia. With the outbreak of World War I the era of modern thoracic surgery commenced. During the years 1910-1920 thoracic operations were mostly procedures for the drainage of empyema and lung abscess. There was, however, some interest in thoracoplasty for pulmonary tuberculosis. Advances between 1920 and 1940 followed improvements in anesthetic techniques, increased knowledge of respiratory physiology, control of shock, blood transfusions, maintenance of fluid balance, and chemotherapy. Improved methods for the treatment of suppurative diseases of the lung were developed.

In 1923 Fvarts Graham described his operation "pneumonectomy with cautery" which was actually a resection of a portion of lung tissue. This method persisted for the excision of suppurative lung tissue until 1929 when Harold Brunn successfully devised an improved technique of lobectomy for bronchiectasis. The mortality and morbidity have since been greatly lowered with the use of chemotherapy and the antibiotics. Before 1933 there were only six recorded cases of lobectomy for carcinoma of the lung with one-year survival. The first successful pneumonectomy was performed by Nissen in 1931 on a patient with bronchiectasis. Fvarts Graham performed the first successful pneumonectomy for lung cancer on February 27, 1933, and the patient is alive and well to day. At present the operation carries a relatively low mortality rate.

Surgery of pulmonary tuberculosis advanced during the 1920's, more rapidly than other thoracic surgery. The collapse therapy methods of Sauerbruch of Germany were advanced and practiced on this continent by Edward Archibald, John Alexander, and others. With the discovery of antituberculosis drugs, early segmental resection and lobectomy are now being advised.

The field of thoracic surgery is continually expanding and has progressed from a restricted specialty to one which includes many safe and effective procedures.

Cardiovascular Surgery

Cardiac surgery until recently was very limited. In 1913 Rehn and Sauerbruch operated

for constrictive pericarditis. There were early attempts to explore the cardiac valves. Doyen in 1913 operated for pulmonary stenosis and Tuffier in 1914 was temporarily successful in digitally dilating an aortic stenosis. From 1923-1928 Cutler, Levine, and Beck operated upon patients with mitral stenosis, using a tenotome and modifications thereof. Also in 1925 Souttar performed a successful digital valvulotomy for

In 1951 Dubost excised an aneurysm of the lower end of the aorta with replacement of that portion by an homologous graft. Since that time there have been many contributions to the operative treatment of thoracic aneurysms. Such operations have been greatly facilitated by the establishment of banks for the preservation and distribution of homologous arterial grafts.

Neurosurgery

lowed by the work of Bailey, Harken, and others. New techniques are rapidly developing in cardiac surgery, one of the most recent of which is the extracorporeal pump. This apparatus, pioneered by John Gibbon, Jr., and others, is continually undergoing improvements and holds much promise for open cardiac surgery. Successful cases are being reported with greater frequency.

The surgical treatment for coronary occlusion was begun in 1932 by Claude Beck, who has been perfecting various methods for myocardial revascularization. O'Shaughnessy's use of omental grafts soon followed. Recent developments include Beck's shunt from the aorta to the coronary sinus, and Vineberg's internal mammary artery implant.

The groundwork for vascular surgery was laid by Alexis Carrel's work from 1900-1910. In 1905 he developed a method of blood vessel anastomosis, and in 1908 he reported the successful transplantation of a 30-day preserved segment of a dog's aorta into the aorta of another dog. During this time Rudolph Matas and William Halsted were pioneering in the surgical treatment of aneurysms.

In 1938 Gross reported the first successful ligation for patent ductus arteriosus. Blalock in 1945 successfully operated upon a patient with tetralogy of Fallot by anastomosing a branch of the aorta to the pulmonary artery, also in 1945 Crafoord and Gross independently reported a successful resection for coarctation of the aorta. In 1946 Potts described the side-to-side anastomosis of the aorta to the pulmonary artery for the tetralogy of Fallot.

There have been most rapid advances in blood vessel surgery. Vessel grafts are now being used after resection of vascular lesions.

The modern development of neurosurgery in Britain and America commenced with Victor Horsley and Harvey Cushing. Horsley's approach was along anatomic and physiologic lines, while Cushing contributed to the technical aspect. Following the work of Hughlings Jackson on focal epilepsies and David Ferrier on cerebral localization, Horsley independently continued these investigations. He contributed extensively to cerebral localization and his experiments on the anthropoid brain were most valuable. Based on William Halsted's teachings, Cushing developed a meticulous neurosurgical technique which has become the accepted method. He then applied himself to brain physiology and conducted experiments on the anthropoid brain.

Present-day neurosurgery is possible because the surgeon has a better knowledge of neurology and improved methods of radiologic diagnosis and a better understanding of the pathology and biologic behavior of tumors, as well as more adequate surgical techniques. Ventriculography, introduced in 1918 by Walter E. Dandy, made possible more accurate localization of intracranial lesions than had hitherto been possible. Myelography holds a similar place in spinal surgery.

Cerebral angiography, developed and reported by Egas Moniz in 1931, has revealed numerous vascular tumors and anomalies. Electroencephalography, reported by Hans Berger in 1929, and further developed by F. A. Gibbs and H. H. Jasper, has become an important technical method in the field of cerebral localization; it is of the utmost value in the treatment of epilepsies and is also of diagnostic significance.

Technical methods have advanced with improvements and newer techniques in anesthesia, the availability of adequate suction, electrosur-

1921 for the diagnosis of adrenal tumors; this has been replaced by presceral insufflation. Renal aortography was utilized in 1929 for the diagnosis of renal cysts and tumors. There have been great changes in therapy. The management of renal tuberculosis has been greatly improved by the use of antituberculous drugs in association with nephrectomy.

Among the advancements in bladder surgery has been the construction of substitute bladders. In 1930 Culbert and his associates devised an operation utilizing the cecum and ascending colon. Bricker introduced another method in which an isolated loop of terminal ileum is used as an ileal bladder. These methods offer promising possibilities.

The outstanding contributor to prostatic surgery since 1900 has been Hugh Young, who perfected the 'punch' operation and developed the perineal operation and radical procedures for prostatic carcinoma. In addition to the development of the perineal, suprapubic, and retro-pubic methods of prostatectomy, there has been great interest in transurethral resection, which for practical purposes dates from 1909 when Young introduced the urethrosopic prostatic excisor. There have been many modifications in the 1920's and with the development of the Stern-McCarthy visual electrotome, great interest was aroused and many improvements followed. This is now a well established form of treatment for certain prostatic cases. A new approach to the treatment of prostatic cancer was introduced in 1939 by Huggins' work on the endocrine features; this resulted in the use of bilateral orchiectomy for inoperable prostatic carcinoma. Recently Huggins has been studying the relationship of the pituitary and a gland to this condition.

Thoracic Surgery

The foundation for modern thoracic surgery was laid, with attempts to control pneumothorax in open operations of the chest, by Ferdinand Sauerbruch with his negative pressure cabinet and Wiltz Meyer with a positive pressure apparatus. Sauerbruch's cabinet, introduced in 1933, weighed 10,000 pounds and required that the patient and the operators be in the enclosure with their heads outside. The problem was solved in 1909, when

S. J. Meltzer and J. Aver introduced positive pressure endotracheal anesthesia. With the outbreak of World War I the era of modern thoracic surgery commenced. During the years 1910-1920 thoracic operations were mostly procedures for the drainage of empyema and lung abscess. There was, however, some interest in thoracoplasty for pulmonary tuberculosis. Advances between 1920 and 1940 followed improvements in anesthetic techniques, increased knowledge of respiratory physiology, control of shock, blood transfusions, maintenance of fluid balance, and chemotherapy. Improved methods for the treatment of suppurative diseases of the lung were developed.

In 1923 Everts-Graham described his operation "pneumonec-tomy with cautery," which was actually a resection of a portion of lung tissue. This method persisted for the excision of suppurative lung tissue until 1929 when Harold Brunn successfully devised an improved technique of lobectomy for bronchiectasis. The mortality and morbidity have since been greatly lowered with the use of chemotherapy and the antibiotics. Before 1933 there were only six recorded cases of lobectomy for carcinoma of the lung with one-year survival. The first successful pneumonec-tomy was performed by Nissen in 1931 on a patient with bronchiectasis. Everts-Graham performed the first successful pneumonec-tomy for lung cancer on February 27, 1933, and the patient is alive and well today. At present the operation carries a relatively low mortality rate.

Surgery of pulmonary tuberculosis advanced during the 1920's, more rapidly than other thoracic surgery. The collapse therapy methods of Sauerbruch of Germany were advanced and practiced on this continent by Edward Archibald, John Alexander, and others. With the discovery of antituberculosis drugs, early segmental resection and lobectomy are now being advised.

The field of thoracic surgery is continually expanding and has progressed from a restricted specialty to one which includes many safe and effective procedures.

Cardiovascular Surgery

Cardiac surgery until recently was very limited. In 1913 Rehn and Sauerbruch operated

for constrictive pericarditis. There were early attempts to explore the cardiac valves. Doyen in 1913 operated for pulmonary stenosis and Tuffier in 1914 was temporarily successful in digitally dilating an aortic stenosis. From 1923-1928 Cutler, Levine, and Beck operated upon patients with mitral stenosis, using a tenotome and modifications thereof. Also in 1925 Souttar performed a successful digital valvulotomy for mitral stenosis. For approximately the next 25 years there was no appreciable advancement until Horace Smithy intensified the surgical approach to valvular disease. This was soon followed by the work of Bailey, Harken, and others. New techniques are rapidly developing in cardiac surgery, one of the most recent of which is the extracorporeal pump. This apparatus, pioneered by John Gibbon, Jr., and others, is continually undergoing improvements and holds much promise for open cardiac surgery. Successful cases are being reported with greater frequency.

The surgical treatment for coronary occlusion was begun in 1932 by Claude Beck, who has been perfecting various methods for myocardial revascularization. O'Shaughnessy's use of omental grafts soon followed. Recent developments include Beck's shunt from the aorta to the coronary sinus, and Vineberg's internal mammary artery implant.

In 1946 Potts described the side-to-side anastomosis of the aorta to the pulmonary artery for the tetralogy of Fallot.

There have been most rapid advances in blood vessel surgery. Vessel grafts are now being used after resection of vascular lesions.

In 1951 Dubost excised an aneurysm of the lower end of the aorta with replacement of that portion by an homologous graft. Since that time there have been many contributions to the operative treatment of thoracic aneurysms. Such operations have been greatly facilitated by the establishment of banks for the preservation and distribution of homologous arterial grafts.

Neurosurgery

The modern development of neurosurgery in Britain and America commenced with Victor Horsley and Harvey Cushing. Horsley's approach was along anatomic and physiologic lines, while Cushing contributed to the technical aspect. Following the work of Hughlings Jackson on focal epilepsies and David Ferrier on cerebral localization, Horsley independently continued these investigations. He contributed extensively to cerebral localization and his experiments on the anthropoid brain were most valuable. Based on William Halsted's teachings, Cushing developed a meticulous neurosurgical technique which has become the accepted method. The field of thoracic surgery is continually expanding and has progressed from a restricted specialty to one which includes many safe and effective procedures.

Cardiovascular Surgery

Cardiac surgery until recently was very limited. In 1913 Rehn and Sauerbruch operated

The surgical treatment of both the infective and traumatic disorders of the hand was late in its development. Kanavel placed the therapy of hand infections on a sound basis, and during and following World War II, Bunnell and his co-workers standardized practically every aspect of the primary and secondary procedures for the traumatized hand.

The investigations of tendon anatomy and physiology by Biesalski and Mayer, Bunnell, and others have led to an atraumatic technique. This has contributed largely to the success of transplant procedures for the correction of paralytic deformities and the repair of traumatized tendons of the hand and other parts of the body.

Plastic Surgery

Although some aspects of plastic surgery have been practiced for many centuries, it developed into a separate specialty during World War I. Subsequently its leading exponents in

various countries created centers for system training.

During World War II great progress made in the more physiologic treatment of burn shock. The advent of antibiotic agents assisted in the control of the associated infection. Treatment by exposure superseded the occlusive pressure dressing except for certain regions such as the hand. The development of the dermatome by Padgett enabled the surgeon to readily resurface third-degree burns.

The observation that homografts survive permanently in patients suffering from congenital agammaglobulinemia has spurred research into methods of obtaining survival of homologous grafts of tissues and organs.

General adoption by plastic surgeons of the LeMesurier procedure for cleft lip repair greatly improved the esthetic results obtained. Recently devised operations for repair of cleft palate have resulted in better function of speech.

Fig. 4—Present-day surgery under the television camera. (Courtesy Smith, Kline & French Laboratories, Montreal, Canada)

gery, and better hemostasis. Consequently more conditions are now being treated.

Recently psychosurgery, the surgical intervention for the relief of psychoses, previously considered hopeless, has been developed. These operations are declining in frequency as a result, in part, of new drugs.

Traumatic and Orthopedic Surgery

Like surgery in general, orthopedics was profoundly influenced by two world wars. In both conflicts there were numerous injuries to the extremities which led to new and better methods of treatment. It has been stated that orthopedic surgery as we know it today had its birth in World War I and became of age in World War II.

At the end of the 19th century, orthopedists were concerned mostly with deformities of the spine, tuberculosis of bone and joint, clubfeet, and congenital dislocation of the hip. While there was a trend toward operative surgery in addition to mechanical therapy, there were many orthopedists adhering to the principle of braces and mechanotherapy alone.

By the beginning of the present century operative surgery was gaining momentum. Among its pioneers were Arbuthnot Lane, Albin Lambotte, Fred Albee, and Russell Hibbs. In the last decade of the 19th century and early part of the present century, Lane and Lambotte developed the treatment of fractures by open operative reduction and mechanical fixation of the fragments. The former introduced the metal-touch technique for the insertion of the metallic plates and screws. This method fell into disuse until the introduction of the inert metals following the researches of Venable and Stuck in 1937, which obviated the associated foreign body reaction of bone to the corroding metal previously employed. This, together with the use of antibiotics and improved standards of surgical technique, has firmly established the open operative treatment of fractures.

The application of this method is well seen in the treatment of the so-called "unsolved" fracture, i.e., of the neck of the femur, which was revolutionized in 1931 when Smith-Petersen introduced the three-flanged nail for its internal fixation. A further development for fractures of the shafts of long bones such as

the femur was the use of intramedullary splinting, employing a nail developed by Kuntscher in 1938.

The independent development of bone graft surgery by Albee and Hibbs has also led to great progress, chiefly in relation to spinal fusion and to nonunion of fractures. In recent years bone banks have been established for the preservation of refrigerated homologous bone.

Orthopedic surgery was firmly established as a specialty in Great Britain, largely due to the influence of Robert Jones, who disseminated the ideas of Hugh Owen Thomas. In addition to his many other contributions and outstanding work on joint injuries, he was responsible, after World War I, for the inclusion of the treatment of fractures as a part of British orthopedic practice.

The outstanding contribution to the functional treatment of fractures was made by Bohler. He stressed the concomitant treatment of the soft tissues. His ideas were disseminated in the English-speaking world by the translation of his textbook by Hey Groves and later by the inclusion of his ideas in the well-known text of Watson-Jones.

In recent years advances have been made in many directions. Arthroplastic procedures, especially in relation to the hip joint, have undergone many changes. In 1939 Smith-Petersen developed the Vitallium mold arthroplasty. The acrylic replacement of the femoral head, popularized by Jean and Robert Judet, has rapidly been replaced by prostheses of inert metal with an intramedullary shaft. Evaluation of such prostheses still remains to be determined.

Our understanding of spinal disorders with referred segmental pain has been enhanced by the practical application by Mixter and Barr of Schmorl's studies of the intervertebral disc. Most cases of lumbosacral pain and sciatica are now known to be due to disc degeneration and prolapse.

Our knowledge of shoulder lesions rests on the fundamental studies of Codman and Bankart, who established the underlying bases for the clinical disorders of the rotator cuff and for the recurrent dislocation of this joint. To Codman must also be given the credit for establishing the American Registry of Bone Sarcoma, which is based on the modern concepts and treatment of these malignant neoplasms.

Hand surgery has developed as a specialty which combines the skills of the general, orthopedic, neuro-, and plastic surgeon. The use of skin grafts, pedicle flaps, and bone cement, combined with cancellous grafts and nerve suture, has salvaged many mutilated hands.

Plastic surgery, in conjunction with other specialties, has become interested in the problems of geriatric patients and has helped in solving the difficulties arising from neoplastic disease, mainly of the head and neck.

THE TRAINING OF A SURGEON

While surgery has developed by a process of evolution from an art to a science, the training of the surgeon has also changed. The surgeon should have a thorough grounding in the Humanities before he seeks a knowledge of the basic sciences, physiology, anatomy, biochemistry, bacteriology, and before he attempts to coordinate pathology, roentgenology, and internal medicine. In an address before the Royal College of Physicians and Surgeons of Canada, Van Wyck aptly emphasized the importance of the Humanities as part of a medical education. "Thus, the humanities promise much more than a mere living. They promise life, wisdom, a spiritual concept of existence, freedom of intellect and will, and the fruitful development of men's ineradicable religious instinct. And of these interests and studies of man, let us choose the three greatest because they include all the others—literature (especially poetry), history, and the arts." Sir Heneage Ogilvie stated, "There are at least four stages in the forming of a surgeon: he must be found, he must be qualified, he must be trained, and he must be given opportunities." Of the four, the training stage requires further consideration.

The doctor who plans a career in surgery must have a definite schedule of postgraduate training. In addition the course should be planned to meet the requisites of the various certification boards. A suggested minimum course should include six months in hospital, one year of internship in an approved hospital, and two and one-half years in general surgery in an approved hospital. Those who plan to undergo a more thorough training and receive a Fellowship in one of the colleges should in

addition, include a year in one of the basic sciences or experimental surgery, a year at various clinics, and a residency in surgery.

Finally improved methods of visual surgical education are being developed by means of the motion picture and television. The surgical societies and the medical schools are gradually building up libraries of valuable teaching films. In some centers operations are being televised. The advantages of this medium are obvious.

In addition to a scientific training, a surgeon must possess and develop fine qualities of mind and body. Hutchison has beautifully described the attributes of a surgeon in his address to the students of the London Hospital Medical College, entitled "Seven Gifts."*

"Good health that sort of wiry constitution which is able to resist fatigue and infection"

"Luckiness pure luck is one of the chief factors making for happiness and success. Some men owe all or nearly all their success to luck, but if you have it not, remember that hard work and patience can make up to a great extent for the want of it."

"Brains but not too many. It is unnecessary—perhaps dangerous—in medicine to be too clever. But if I had not many brains to bestow I should make up for it by an extra gift of diligence."

"Equanimity there is no quality of mind more essential to you as doctors, for you will often have to face sudden and disconcerting emergencies and a fair share of it will also do much to preserve you from the corroding effect of those worries which are unescapable in practice."

"A sense of justice in the first place to your patient—Justice also to your professional brethren—and lastly a sense of what is just to yourself."

"A sense of beauty. Disease is ugly. You will need a sense of beauty as a compensation and a way of escape, as a sanitizing and steadying influence."

"My last and best gift would be a sense of humor. It will help you to bear with the vagaries of your patients and still more with those of their relations and to derive amusement instead of annoyance from the eccentricities of your colleagues."

Armed especially with the last three, a sense of justice, of beauty and of humor, you will be able to face with equanimity all the buffets and disappointments, all the weariness and ugliness which your lives as doctors may have in store for you.

Inflammation and Repair

Gardner C McMillan, MD

The reactions of the body to injury may be localized or generalized. The localized reaction to injury is called *inflammation*. The generalized reaction has not been given a special name. It arises when the local reaction is sufficiently great or when the injurious stimulus does not remain sufficiently localized. Both the local and general reactions are complex and may find variable expression. Inflammation is divided into simple and granulomatous types. The generalized reaction is not so clearly categorized but is designated by such terms as shocked, toxic, stressed, adaptive, febrile, allergic, etc.

Among the reactions of the body to injury is that of *repair*. It is a local reaction the effect of which is to restore injured tissue and its function. It is frequently maintained that repair is an end stage of inflammation, but there is little justification for this view. Whereas inflammation results in the neutralization or removal of injurious agents and effects the disposal of dead tissue, repair has no direct action on injurious agents; indeed it is inhibited by them, and it fills the defects left by injury and inflammation. One of the cardinal signs of inflammation is loss of function, the effect of repair is a restoration of function. The subsidence of inflammation is followed by repair, but specialized forms of repair such as compensatory hypertrophy can occur in the absence of inflammation at the site of hypertrophy. It would seem reasonable to recognize that, while inflammation and repair frequently seem intimately related, they are separate processes of function.

mentally different nature arising in response to fundamentally different stimuli.

It should not surprise the reader to find that this concept is opposed to that expressed in the previous editions of this textbook. Professor T. R. Waugh wrote: "Moreover, some pathologists include under inflammation only that part of the local changes which is of exudative character, while all proliferation of cells and fibrosis taking place at the site of the injury to them constitute repair. These difficulties and differences arise from a didactic and teleological approach to the subject. The cells of the body at the point of injury undergo regressive and progressive changes purely as the result of their natural reaction to alterations in their environment. These individual cell responses may or may not be beneficial to the body as a whole. Very different combinations of these cell reactions are met with in the various types of inflammation, and many of the same cell changes are encountered in repair. To assume that the fibroblasts proliferate in one case to check the spread of an infection and in another to replace damaged tissue is drawing a purposeful distinction. Consequently, any attempt to sharply define inflammation and repair as separate processes must fail. The view of necessity fall down on natural grounds." The view expressed by Dr. Waugh is held by many pathologists. However, I, along with other pathologists, hold that repair is related to cellular generation, growth, and differentiation rather than to inflammation. I would maintain that the fundamental biologic phenomena of repair are related to those encountered in the study of embryology, of growth, or of neoplasia rather than to those of inflammation, and I regard it as a conceptual error to fail to distinguish between inflammation and repair.

*Wauagh, T R In Mosely, Textbook of Surgery, eds 1 and 2, St Louis, 1932, 1935, The C. V. Mosby Co., chap 2

A debate on these views cannot be undertaken here. Suffice it to point out that the very coexistence of such radically different concepts as those expressed above is a measure of how great is our ignorance about some of the fundamental principles of inflammation and repair.

SIMPLE INFLAMMATION

The immediate causes of inflammation must injure the tissues. The causal agents may be *physical* in nature, such as heat, cold, mechanical injury, or radiant energy, or *chemical* and caustic, corrosive, or poisonous. *Living agents* such as *microorganisms* or *parasites* are usually separately classified as causes of inflammation because of their special behavior in relation to the host and their ability to live and multiply in the host and to induce immunologic reactions.

The essential reactions of simple inflammation are an orderly sequence of events. The process is remarkably similar from example to example. It does not vary, except in detail, from patient to patient, from site to site, or under different etiologic circumstances, however, some of the variations in detail may be of clinical importance. The orderly and progressive inflammatory process may halt at any stage of its development and regress. It does not always go through its entire sequence of stages, although their order is constant. The latter stages of the process cannot occur in the absence of the earlier ones.

VASCULAR REACTIONS IN INFLAMMATION

In simple inflammation vasomotor effects and consequences are of very great importance. The process begins, if the insult is abrupt enough and affects a sufficient region, with a momentary vasoconstriction, which is followed by capillary and arteriolar dilatation. The region is the site of an active hyperemia and is redder than normal. If the injury is on or close to an external or peripheral part of the body, the lesion will be warmer than usual. Further capillary dilatation, with or without some subsequent arteriolar narrowing, causes a reduction in the linear rate of blood flow through the capillary bed, although the volume of flow continues to be greater than normal. The lesion is reddened, perhaps slightly cyanosed, and less

warm than previously. It will be surrounded by a margin of active hyperemia that remains a brighter red color. This is a peripheral zone where the capillary bed is less markedly dilated and where the flow remains relatively rapid.

Concomitantly with these phenomena the capillary endothelium becomes swollen and presents an increased resistance to the flow of blood along the capillaries. It also, while retaining some semipermeable qualities, becomes more permeable to fluids and crystalloids and allows larger molecules to pass through its wall in greater quantities than normal. These reflections of capillary injury are accompanied by the transfer of an increased amount of fluid and protein to the interstitial spaces and by a further reduction in the rate of blood flow in the dilated capillary bed. Capillary blood sludging or coagulation may occur in some vessels. The fluid that escapes into the interstitial area flows on the surfaces of cell membranes and fibrillar strands at first but soon diffuses freely into the ground substance gel and renders it more fluid. A new equilibrium is established between the outflow of fluid from the capillaries, interstitial edema, fluid return to venular capillaries, and lymphatic drainage. The site of injury is swollen.

The vasomotor effects of simple inflammation in the skin have both chemical and nerve reflex mechanisms. Sensory stimuli carried along axons from the area of injury pass antidromically to the arterioles about the area and cause them to dilate. Abolition of the axon reflex will prevent development of some of the active hyperemia normally associated with cutaneous inflammation so that the site fails to develop a prominent peripheral flare. The nervous system also exercises some control over the inflammatory response in a more general vasomotor effect. It is observed that section of sympathetic nerves with relaxation of vasoconstriction enhances inflammatory effects, while the abolition of vasodilator action restricts inflammatory processes. These more general aspects of nervous control, however, are not fundamental to the inflammatory process. The axon reflex is thought to be initiated by a histamine-like substance or substances acting on sensory nerve endings. Histamine-like material, the so-called *H substance*, is released by cells at the local site of injury. It affects directly the walls

of capillaries and minute vessels to cause their vasodilatation. It is the direct action of the histamine-like material on these blood vessels that is responsible for capillary dilatation and the consequent capillary hyperemia and slow rate of blood flow in the affected region. This hyperemia causes a dull red color in the central area of injury.

As we have noted, the vasomotor effects of inflammation, unless they are very slight, are accompanied by an increased permeability of the affected capillaries and by local edema. The causes of increased capillary permeability are not entirely established. Immediate effects are probably due to H substances for it can be shown that histamine not only causes vasodilatation but also rapidly increases capillary permeability to dye substances injected into the blood stream. A similar increase in capillary permeability results from a substance or substances found in inflammatory exudates and called *leukotaxine*. It is observed that crude leukotaxine causes endothelial swelling, increased capillary permeability, and emigration of leukocytes from blood vessels. The material appears to result from the partial lysis of protein and to be a mixture of peptides. It has been shown that peptides composed of a chain of 8-14 amino acids will cause increased permeability. They may be responsible for the increased permeability of prolonged inflammation but, since their formation is relatively slow, will not account for the immediate or H-substance effect. It should be remembered that the hemodynamic changes occurring in the capillary bed tend to increase the capillary blood pressure and hence to promote the passage of fluid from the capillary and to hinder its return at the venous end of the capillary. Similarly, with the escape of a fluid containing more protein than usual, the normal differential in osmotic pressure between the plasma and the interstitial fluids tends to decrease. Moreover, the capillary membrane itself is no longer so effective in the creation of osmotic effects. All of these phenomena tend to cause local edema.

CELLULAR REACTIONS IN INFLAMMATION

As the vascular phenomena described above develop and persist, the emigration of leukocytes from the blood to the interstitial tissues

occurs. The cellular reactions of inflammation first affect the local tissue histiocytes. These are phagocytic cells that belong to the reticuloendothelial system and occur in variable numbers in the connective tissues of the body. They have little ability to migrate and only a relatively modest proliferative activity. However, they are avid phagocytes and they constitute the first cellular line of defense in inflammation. They are rapidly stimulated in simple inflammation. In those areas where they are numerous, bacterial inflammations may be quickly confined and terminated.

If the inflammatory process progresses, emigration of leukocytes from capillaries occurs. The polymorphonuclear neutrophilic leukocytes are the first cells to do this. They are followed by mononuclear leukocytes within an hour or two, and many investigators believe that during the subsequent several hours very numerous lymphocytes also emigrate and rapidly transform into mononuclear macrophages. Cycles or waves of cellular emigration may occur. The phenomenon begins as the capillary endothelium becomes swollen and altered, the linear rate of blood flow slows, and as endothelial permeability increases. Leukocytes tumbling over the surface of the endothelium tend to adhere to swollen endothelial cells and intercellular cement substance. There occurs a margination or pavementing of leukocytes, especially neutrophil polymorphonuclear cells, on the walls of the capillary vessels. If the injury is sufficient, many of these cells will migrate by amoeboid movement through the capillary wall between endothelial cells. Their passage is aided by the intracapillary blood pressure.

The direction of motion of migrating leukocytes may be influenced by the presence of substances that are said to be chemotactic. *Chemotaxis* is a phenomenon of obscure mechanism but of widespread biologic occurrence. It is exhibited by such things as the spermatozooids of certain plants, by certain myxomycetes, amoebae, and other organisms, as well as by leukocytes of various sorts in various species of animals. There is little reason to believe that the pavementing of leukocytes or their emigration from the capillaries is influenced by chemotaxis, since there is no evidence that chemotactic material can act across the wall of the blood vessel. However, it remains possible

septa within the abscess of the fat-pad need division with a scalpel (fig. 58). The lips of the cutaneous incision should be trimmed elliptically to prevent premature closing of the skin.

Deep Plantar Abscess.—The central plantar space situated deep in the plantar fascia is arranged like an apartment house of four stories, each of which is occupied by the muscles that constitute the flexors of the toes. Infection of the various floors becomes increasingly less common as one proceeds from the ground floor, upwards. For drainage of the central plantar space an incision parallel to, and just above, the medial border of the foot in the neighbourhood of the instep, is made (fig. 59).

FIG. 59.—Incision for draining the central deep plantar space.

Infections of the Dorsum of the Foot

The dorsal subcutaneous space usually is infected by extension from a subcutaneous interdigital space or a web space, while the dorsal subaponeurotic space is infected either from a direct puncture or from involvement by extension from the deep plantar space. To drain the former space the incision should be placed distal to the dorsal venous arch, but in the line of the digital vessels and nerves, in order to avoid them. To drain the latter space it is best to confirm the presence of pus by attempting aspiration, and if diagnostic aspiration is positive, to make a longitudinal incision alongside the needle. Leprosy not infrequently attacks the toes, and the initial manifestation may simulate a chronically infected corn (fig. 60). Leprosy is discussed on p. 25.

FIG. 60.—Leprosy of the little toe (O. D. Adams, F.R.C.S. Bombay)

FIG. 61.—Madura foot. (Dr. M. M. Schapiro, Honduras)

Madura foot (syn. mycetoma pedis) is a chronic granulomatous disease encountered especially in tropical countries, notably in certain parts of India but with increasing frequency in territories where hitherto it has been unrecognised, such as the Southern United States, South America, and Cuba. The disease is caused by a genus of filamentous fungus (*Osipora madurae*) resembling actinomycosis and abounding in road dust. In nine out of ten cases the organism gains entrance through a prick in those who go about barefooted. The first manifestation is a firm, painless, rather pale nodule. Soon other nodules appear. Later the nodules become surmounted by vesicles that burst to form discharging sinuses. In the watery discharge granules can be discovered, sometimes only with perscverance. On some

that pavementing of leukocytes occurring at the venous end of the capillary, where fluid is returning across the vessel wall from the interstitial region to the blood, might be enhanced by chemotaxis, and it is possible that leukocytes that have already migrated partially across a capillary membrane to lie both within and without the capillary may be directed to complete their emigration by chemotaxis. In any case, the role of chemotaxis becomes definite once the responsive leukocytes gain the interstitial spaces. Many substances appear to exert a chemotactic influence on leukocytes, and many bacterial and such a substance as starch grains possess this quality. On the other hand, there are differences of opinion as to whether or not dead tissue and tissue products resulting from autolysis or partial enzymatic digestion may be chemotactic for leukocytes. In this connection it may be noted that the prominent chemical necrosis of cells in the pancreatic islets that follows an intravenous injection of alloxan into experimental animals occurs without any emigration or accumulation of leukocytes. Indeed within 24-48 hours after such an injection, many necrotic cells have been entirely removed from the islets without the participation of leukocytes. Similarly in the human aorta diseased by medionecrosis, an appreciable amount of necrotic tissue may be seen in the media of the aorta in the absence of any leukocytic accumulation.

With the emigration and accumulation of leukocytes the inflammatory process has reached its full development. More emigration of cells may occur with suitable stimulation, but further changes involve the phagocytosis of particulate material, the disintegration and disappearance of polymorphonuclear leukocytes, the disappearance of mononuclear cells of various sorts, and the subsidence of the vascular phenomena. In the course of these changes host tissue may be destroyed and removed and pus may form and be absorbed or require drainage. The final regressing phases coincide with the initiation of healing.

Whether or not one regards the inflammatory process as purposive, its elements have certain predetermined effects in the local area of reaction. The vascular phenomena are essential to the formation of the fluid and cellular exudates. Hyperemia and the accompanying

edema serve to dilute and flush away toxic substances and waste materials. Hyperemia and edema increase the circulation of antibodies, nutrients, and antibacterial drugs in the area. As capillary permeability increases, large molecules such as fibrinogen escape into the tissues and fibrin may precipitate interstitially. The formation of a fibrin clot in the tissues assists phagocytes to capture and engulf particulate matter by surface phagocytosis. It also provides a partial mechanical barrier to the spread of infection and may reduce drainage of fluid from the lesion.

Role of the Cellular Exudate

The function of the several types of cells that participate in simple inflammation is not well understood. The *tissue histiocytes* are phagocytic to particulate matter and bacteriocidal for most organisms. They may successfully contain and limit an appropriate etiologic agent; obviously they cannot do this if the causal agent of the inflammation is a true chemical solution, a mechanical force, or is radiant energy. The *neutrophil leukocytes* emigrate promptly, are actively motile, and are phagocytic and bactericidal for many bacteria. Their life span in an inflammatory focus is 3-5 days or less. Many of them disintegrate rapidly to release their enzymes into the milieu of the reaction, assisting in the digestion of protein matter and forming pus. Others round up, acquire a pyknotic nucleus, and appear somewhat like lymphocytes in histologic preparations. If the region of inflammation is sufficiently large or if it is a smaller lesion that cannot drain but develops in the tissues under pressure, a systemic leukocytosis may occur. The products of certain bacteria, nucleoprotein, and possibly cytoplasmic breakdown products absorbed from the lesion are effective stimulants to cause leukocytosis, but the mechanisms of leukocytosis in inflammation are not understood. *Eosinophil leukocytes* are mobile, attracted by chemotaxis, and phagocytic. Their function in the body is not known in detail. Eosinophil leukocytes appear especially in inflammatory reactions of allergic etiology, but they are not limited to them. For example, in the inflammatory reaction occurring in acute myocardial infarction a brief influx of eosinophil leukocytes

is observed (see Fig. 5) The blood monocytes emigrate into inflammatory foci in considerable numbers and transform with considerable speed into large macrophages. They respond to chemotactic substances in much the same way as neutrophil leukocytes and may show an especially strong attraction to organisms such as *Mycobacterium tuberculosis*. They are phagocytic, bactericidal for many bacteria, and tend to survive as scavengers. They are

capable of multiplication at the site by mitotic division. They either migrate away from a subsiding area of inflammation, remain as tissue macrophages fixed in the area, transform to epithelioid cells, to giant cells, or possibly to fibroblasts, or they may disintegrate. The function of lymphocytes in inflammatory lesions is a subject of debate. Many pathologists believe that their local function is unknown; others, the author among them, maintain that lympho-

Fig. 5 The diagram represents some of the sequence of events that occurs at the site of a myocardial infarct. Following ischemic infarction and the death of a portion of myocardium there develops locally a simple acute inflammatory reaction. There is an emigration of neutrophil leukocytes that reaches its height within about 4 days and subsides in about 3 weeks. The removal of debris from the infarcted region is apparent about 3 days after infarction, it reaches its height in about 2 1/2 weeks and may continue for several months. Occasionally in large infarcts a sequestrum of dead tissue may be left. Eosinophil leukocytes are seen in the lesion during the second and third weeks. Macrophages become prominent in the lesion toward the end of the first week, and are most numerous between the third and fourth weeks. A small number of macrophages, some of which may contain hemosiderin, and lymphocytes may persist in the lesion for many months. Fibroblastic proliferation can be seen within a few days after infarction, appreciable production of collagen begins during the second week, increases rapidly during the third week, and is almost completed within 3 months following infarction. The interval of time that must elapse before collagen formation is completed will depend on the size of the infarct. The scar that is formed is always smaller in volume than the portion of myocardium that was infarcted. (Based on the data of Mallory, G. E. White P. D., and Salcedo, Salgado, J. *Am. Heart J.* 18, 647, 1939.)

cytes emigrate in large numbers from the blood in inflammatory foci, where they are rapidly transformed into large phagocytic cells that soon become indistinguishable from other phagocytes derived from the transformation of monocytes. In inflammatory foci in which capillary injury is severe, erythrocytes may be present in the inflammatory exudate. They escape passively from grossly damaged capillaries and have no known function in the inflammatory reaction.

The exudative phenomena of simple inflammation may emphasize one or other aspect of the changes of inflammation described above. Certain descriptive names have been applied to these inflammatory reactions. The accumulation of an exudate that is relatively poor in fibrinogen content and that contains few leukocytes is spoken of as *serous*, the addition of macroscopically detectable amounts of fibrin to the fluid because of increased capillary permeability yields a *serofibrinous* exudate, the addition of appreciable numbers of polymorphonuclear leukocytes to the exudate creates a *purulent* or *fibrinopurulent* lesion. The occurrence of capillary damage to the point of partial disruption while circulation continues in the damaged vessels creates hemorrhagic exudates. Inflammatory exudates are most easily characterized in this manner when they occur on some surface (skin, serosa, mucosa) where they are easily visible. When exudates occur in tissue they are usually characterized by different names than when the same reactions are observed at surfaces, e.g., inflammatory edema rather than serous or serofibrinous exudate, suppurative instead of purulent, a rapidly spreading serofibrinous and suppurative reaction in the connective tissues is called a *cellulitis*, a sharply localized focus of suppurative reaction with marked necrosis of host tissue is called an *abscess*. Simple inflammatory reactions may be reduced in intensity, prolonged in time, and accompanied by some healing reactions. These constitute subacute and chronic inflammations.

GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is a form of inflammatory reaction in which vasomotor phenomena are minimal and in which the

primary and essential reacting cells of the inflammatory exudate are mononuclear macrophages. The reacting mononuclear cells are derived from the local tissue histiocytes, from monocytes in the circulating blood, and, many pathologists believe, from the lymphocytes of the blood by transformation. It is not unusual to find an excessive proliferation of fibroblasts accompanying some late phase of the granulomatous reaction; the fibroblastic proliferation is considered as a healing phenomenon and may possibly result from the transformation of some of the large numbers of macrophages present in the inflammatory process.

Unlike simple inflammation, granulomatous inflammation, whether acute, subacute, or chronic, not infrequently has morphologic characteristics that indicate its precise etiology. The lesions are almost always sharply focal. Since granulomatous inflammation shows minimal vascular reactions (indeed lesions may have reduced vascularity as, for example, the tubercles of tuberculosis), some of the cardinal signs of inflammation will be absent. The lesion, however, is swollen. The swelling is due to an accumulation of macrophages in excess of host tissue destroyed so that a tumorlike cellular lesion results. Granulomatous inflammation and granulation tissue formation should not be confused. They have little in common. The former is an inflammatory reaction, is not vascular, is rich in reticuloendothelial cells, is frequently due to a demonstrable bacterial or other exogenous cause, and is, in essence, a destructive pathologic or disease process. The latter is a healing reaction that forms a richly vascular, proliferating fibroblastic tissue, showing minimal or no signs of inflammation, free or almost free from bacteria or exogenous material, and resulting in at least partial restitution of the affected area by the formation of mature connective tissue.

COMMENT ON THE INFLAMMATORY REACTION

We have described inflammation as a local reaction to injury and have implied that it is a constant and orderly process. While this is a valid generalization, it is also true that the inflammatory reaction may be considerably modified by the constitutional and pathologic

status of the patient in whom the reaction is progressing. Some of the aberrations that may occur in the inflammatory reaction are of clinical interest.

SIMPLE INFLAMMATION

Influence of Tissue Structure

The types and numbers of cells that participate in an inflammatory reaction will depend on the nature and site of the tissue affected, on its vasculature, on the nature of the causal agent, and on the patient's hematologic status. Some parts of the body such as the liver, spleen, lymph nodes, and bone marrow contain great masses or filters of tissue macrophages. These are the main organs of the reticuloendothelial system. In them simple inflammation is modified by the presence of enormous numbers of tissue histiocytes. Indeed, so numerous are the phagocytes and so available is their supply that one seldom sees more than a small number of polymorphonuclear leukocytes in a lymph node that is the site of an acute inflammatory reaction. The acutely inflamed node is commonly swollen and soft with lymph fluid and hyperplasia of phagocytic cells, but only uncommonly will it be found to be suppurative. Similarly, the surfaces of the pericardial, pleural, and peritoneal spaces are richly supplied with tissue macrophages and these cells participate generously in simple inflammatory responses. However, in these spaces exudates can spread and accumulate, and since the tissue macrophages are relatively fixed, the cellular accumulation is largely hematogenous in type. It exudes from the rich vascular networks and lymphocytic tissues that lie close beneath the serous membranes. The inflammatory responses of the alveolar sponge of the lung are very much like those of the serosal spaces. The tissue presents an enormous surface area, richly vascularized and abundantly furnished with phagocytic cells. The latter are somewhat mobile and participate vigorously in the inflammatory reaction. However, the inflammatory exudates that spread and accumulate in the alveolar spaces contain chiefly cells of hematogenous origin. There is evidence that the lung, both normally and pathologically,

may act as a remarkable filter for the sequestration of polymorphonuclear leukocytes. This phenomenon will contribute to the cellular population in simple inflammation of the lung. The lung can drain its exudates through the bronchial tree. It is a curious and, so far as one is aware, unexplained fact that exudates of inflammatory cells in joint spaces lined with synovium contain many polymorphonuclear leukocytes, even in chronic disease. In the general connective tissues of the body, as in the subcutaneous tissues, histiocytes are relatively sparse and the cells that participate in simple inflammation are derived in great majority from the blood.

Influence of the Patient's Hematologic Status

Obviously the course of the inflammatory process at any site will depend on the nature and number of cells available. In general, the process is fairly uniform from patient to patient and whatever differences are noted lack apparent explanation. Major and explicable differences are occasionally observed. The most obvious of these occur in patients in whom the hematopoietic organs fail to produce polymorphonuclear leukocytes. In the most severe form of chemically (drug) induced acute agranulocytosis or malignant neutropenia, the polymorphonuclear cells, and to a lesser extent other leukocytes, may be so deficient in the blood that they are absent or nearly absent from foci of acute inflammation. The body's defenses against infection are correspondingly deficient and the patient becomes acutely ill with chills, fever, and mucosal ulceration. Lesser degrees of leukopenia and neutropenia occur under many circumstances, e.g., typhoid fever, measles, malaria, profound septicemia, aplastic anemia, systemic lupus erythematosus, and others, but, in general, the effect on the inflammatory process is clinically slight or negligible. The resultant leukopenia may delay transiently the proportionate accumulation of leukocytes at a site of inflammation, but adequate numbers of cells usually do accumulate rapidly. Nevertheless it may be noted that such leukopenic patients may be more susceptible to infective complications such as furunculosis, pneumonia, and other infective lesions. The larger a focus of

simple inflammation is, the more will it depend on the hematopoietic organs to supply hemogenous leukocytes. In some patients the bone marrow is incapable of responding adequately because it is replaced by fibrosis, by lymphomatous cells, or by carcinoma; the number of leukocytes circulating in the blood may be normal or reduced. An unexplained anergic state of the marrow is not unusual in elderly patients and may be encountered rarely in younger individuals. The number of leukocytes circulating in the blood may be normal and the bone marrow apparently normal, yet these patients do not respond with leukocytosis or with fever to such stimuli as bacterial pneumonia or peritonitis. In such patients the cellular processes of inflammation are initiated, but the usual reaction to injury is not sustained.

It is also observed that the accumulation of cells in a focus of acute inflammation will be partially governed by their proportions in the blood. For example, in rabbits with an experimentally induced blood monocytosis the number of monocytes that enter into an inflammatory focus is roughly proportional to their number in the blood. Similarly, it has been reported that the blood monocytes were an important source of macrophages in a simple inflammatory process in a patient with a form of chronic leukemia in which there were numerous circulating monocytes. The microscopic examination of simple inflammatory foci from patients with a prominent eosinophilia commonly discloses a slight increase in eosinophil leukocytes in the inflammatory lesions. It should be observed, however, that since the clinically significant inflammatory reaction usually lasts several days and since repeated waves of cellular immigration may occur, the proportionate distribution of leukocytes in the blood seldom affects the cellular composition of the inflammatory focus in more than a transient or minor fashion.

Influence of Functional Variations of Leukocytes

Of great interest are those patients in whom the leukocytes are functionally deficient. Leukocytes are complex metabolic units that have numerous enzyme systems and many functions in the body's economy. In the inflammatory

process the ability of leukocytes to migrate to a focus, the ability of monocytes and probably lymphocytes to transform into macrophages, and the phagocytic, bacteriocidal, and proteolytic functions are all of great importance. Similar sorts of leukocytes in different patients are not all identical in these properties. For example, neutrophil leukocytes have a fragility that is said to be inversely proportional to their content of vitamin C; immature granulocytes have little phagocytic activity, although young mature granulocytes are the most effective of phagocytes; there is a decrease of phagocytic activity in animals that are deficient of protein, ascorbic acid, or certain of the B vitamins; excessive amounts of cortisone or corticotrophin adversely affect phagocytosis and diminish the ability of the host to resist invasion by microorganisms; it has been suggested that there may be a deficiency in leukocytic bacteriocidal action in diabetic animals. The most striking deviations in leukocytic function in relation to inflammation are seen in patients with leukemia. Many such patients retain some production and circulation of mature granulocytes and other leukocytes and are capable of producing an inflammatory response. Other leukemic patients may lack sufficient normal leukocytes to respond adequately. A patient with an acute myelogenous leukemia, for example, may possess only primitive cells that migrate slowly, respond poorly to chemotactic stimuli, possess little or no phagocytic activity, have poor bacteriocidal properties, and yield low proteolytic activity. The pathologist is accustomed to see at autopsy what he terms agranulocytic pneumonia or agranulocytic abscesses in such patients. The modification of the cellular reactions of simple inflammation may be so extreme in leukemic diseases as to prevent the formation of pus or the localization of the reaction.

Influence of Vascular Supply

The roles of vasomotor activity, hemodynamic effects, semipermeability of membranes and fluid exchange, and of lymphatic drainage are important in the development of simple inflammation. They may vary to an extent that may markedly influence the general inflammatory process.

Influence of Ischemia

Obviously the acute inflammatory process cannot develop in the usual fashion in an avascular tissue, in a tissue deprived of the circulation of blood, or in an anoxic area. It will be modified by a pre-existing passive hyperemia, by edema, and by factors that affect vasomotor activity or capillary permeability. A large area of ischemic infarction may never show an inflammatory response in its central part because this area is too far removed from the circulation of blood at the periphery of the lesion. Instead, the central necrotic part may remain as a sequestrum or may liquefy. Lesions of this sort may be seen occasionally in large infarcts of the spleen or kidney and in ischemic gangrene of an extremity. The influence of a partial ischemia on the inflammatory reaction can be seen where areas of ischemic necrosis meet viable tissue that has an adequate circulation. The entire simple inflammatory process becomes attenuated and depleted in the more ischemic area. The tissue macrophages fail to function as a first line of defense while the leukocytes and hematogenous macrophages enter the more ischemic zone in reduced numbers and manifest a reduced function. The leukocytes and hematogenous macrophages may wander into the ischemic tissue beyond the threshold of adequate nutritional supply for their own maintenance and themselves die of ischemia. The depletion of inflammatory process to some degree by ischemia is not infrequent. The susceptibility to infection of the arteriosclerotic lower limb, of the lungs in pulmonary fibrosis, or of the skin affected by late changes due to irradiation, is, in part at least, a manifestation of the alteration induced by ischemia in the inflammatory response.

Influence of Edema

Excessive interstitial fluid or edema in an area also attenuates the inflammatory process. Edema fluid is, except for its content of immune bodies, a good bacterial culture medium; it is a diluent of toxins, but also of enzymatic and active substances released in the inflammatory process, it is associated with some degree of reduced blood flow in the area, and in anatomic circumstances where the swelling of

edema is rigidly confined, marked ischemia may result; it increases the distances across which respiratory and nutritional exchanges must occur; its fluid state makes more difficult the capture and surface phagocytosis of particulate matter; by separating tissues and membranes, by diluting the ground substance, and by the flow of its fluid, irritating matter may spread more easily and widely. It is observed that children with the nephrotic syndrome and adults with the nephrotic syndrome and hydropericardium, hydrothorax, and hydroperitoneum may succumb to an intercurrent infection of the fluid-filled serous cavities, commonly with pneumococci. The pathologist sees frequently at autopsy an early pneumonia in association with the hypostatic pulmonary edema that occurs so commonly a few hours or days before death in patients with some degree of terminal cardiac failure. The edematous lower limb of a patient with congestive heart failure and diabetes mellitus is susceptible to infection. An area of sacral edema is particularly liable to decubitus ulcer formation. Such examples of enhanced susceptibility to infection may show that edema may interfere with the inflammatory process, but it should be remembered that the inflammatory process is a complex one. For example, patients with chronic renal failure due to glomerulonephritis are commonly more susceptible to infection whether they are nephrotic or not; patients with ascites due to cirrhosis of the liver or peritoneal neoplasm do not seem especially susceptible to infective peritonitis unless infected during paracentesis; patients with pulmonary edema due to a transient episode of cardiac failure have only a slightly increased susceptibility to pneumonia, the edematous feet and ankles of a patient with congestive heart failure but without diabetes mellitus show only the most minor increase in susceptibility to infection; and patients with the indurated, chronic lymphedema of Milroy's disease probably do not manifest a significant disturbance in the inflammatory process in the affected limb even though lymph drainage is presumed to be deficient. It can be shown in experimental animals that the vasomotor nerves can influence the reaction rates of simple inflammation. For example, sympathectomy with consequent vasodilatation enhances the inflammatory process, while unbalanced sympathetic

nerve vasoconstriction delays and diminishes it. However, in clinical practice these effects seem minor or negligible. The neurosurgeon is not impressed with the enhanced inflammatory reaction in a previously normal limb of a patient who has undergone a lumbar sympathectomy. The vascular surgeon, however, may be considerably impressed with the more normal inflammatory reaction that may be possible following sympathectomy to improve the circulation of a previously ischemic limb.

GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is somewhat simpler in the ebb and flow of its events than simple inflammation. Its relative cellular simplicity and its longer duration often create lesions of specific architecture, yet the process in general shows less of the sort of variability that has just been ascribed to simple inflammation. Nevertheless, examples of such variation are easily found; the susceptibility of the patient with uncontrolled diabetes mellitus or with silicosis to pulmonary tuberculosis is well recognized, although the causes are obscure. In granulomatous inflammation other kinds of variations may be prominent. Granulomatous inflammation is the form of inflammation in which the influences of natural and acquired immunities and hypersensitivities find their most complex morphologic expressions. It is only necessary to point to the enormous clinical and pathologic differences between a first infection and a second infection in pulmonary tuberculosis to demonstrate how effective these influences may be in modifying a granulomatous inflammatory process that is identical in its basic cellular reaction in both forms of tuberculosis. The value of an acquired immunity to tuberculosis is well recognized. It is rather characteristic, but by no means constant, for granulomatous inflammation to be most frequently localized in those tissues and organs that anatomically contain the most macrophages or through which monocytes and lymphocytes migrate in largest numbers. Again tuberculosis provides pertinent examples and exceptions. There is, for example, an unusual and clinically confusing form of tuberculosis in which the lesions are almost entirely confined to the lymph nodes and other reticulo-

endothelial organs of the body, the lesions may be widely disseminated in them. Contrarily, tuberculosis of the skin can occur following direct inoculation. Many of the lesions of granulomatous inflammation acquire importance because of recrudescence or chronicity leading to cumulative injury; many become important because of a multiplicity of small, focal, tumorlike lesions that ultimately obstruct or preclude some body function.

INTERRELATION OF INFLAMMATION AND CHEMOTHERAPEUTIC AGENTS

The nature of the inflammatory reaction to bacteria may influence the chemotherapeutic approach to a disease. Again it is commonly observed that the panoply of the inflammatory process may be obviated by modern chemotherapy. Antimicrobial drugs may be bacteriostatic or bactericidal or both, but in order to be effective they must contact the bacteria in suitable concentration, whether the latter are intracellular or extracellular and whether in viable or necrotic tissue. Some agents, such as the sulfonamides, are essentially bacteriostatic and require the active participation of leukocytes and macrophages for their effectiveness. Other agents, such as penicillin, Terramycin, and tetracycline, are bactericidal and can kill susceptible bacteria without the participation of leukocytes and macrophages, although, of course, all agents will be aided by the ordinary natural and acquired defenses of the body. In the case of many acute bacterial infections in which the bacteria are largely present in the extracellular fluids, where they live and grow, the organisms can usually be rapidly eliminated by suitable antimicrobial drugs. Since no drug kills all bacteria at once but may require several hours or a few days to accomplish this, several days of therapy are necessary. Nevertheless, the inflammatory reaction as such is usually much minimized by such therapy and will subside before its usual course is run. It should be noted that the vascular and permeability effects of simple inflammation that serve to increase the flow of interstitial fluid in an area of inflammation also serve to bring blood-borne chemotherapeutic agents to the site. Indeed, in some cases

nerve vasoconstriction delays and diminishes it. However, in clinical practice these effects seem minor or negligible. The neurosurgeon is not impressed with the enhanced inflammatory reaction in a previously normal limb of a patient who has undergone a lumbar sympathectomy. The vascular surgeon, however, may be considerably impressed with the more normal inflammatory reaction that may be possible following sympathectomy to improve the circulation of a previously ischemic limb.

The vascular surgeon, however, may be considerably impressed with the more normal inflammatory reaction that may be possible following sympathectomy to improve the circulation of a previously ischemic limb.

GRANULOMATOUS INFLAMMATION

Granulomatous inflammation is somewhat simpler in the ebb and flow of its events than simple inflammation. Its relative cellular simplicity and its longer duration often create lesions of specific architecture, yet the process in general shows less of the sort of variability that has just been ascribed to simple inflammation. Nevertheless, examples of such variation are easily found; the susceptibility of the patient with uncontrolled diabetes mellitus or with silicosis to pulmonary tuberculosis is well recognized, although the causes are obscure. In granulomatous inflammation other kinds of variations may be prominent. Granulomatous inflammation is the form of inflammation in which the influences of natural and acquired immunities and hypersensitivities find their most complex morphologic expressions. It is only necessary to point to the enormous clinical and pathologic differences between a first infection and a second infection in pulmonary tuberculosis to demonstrate how effective these influences may be in modifying a granulomatous inflammatory process that is identical in its basic cellular reaction in both forms of tuberculosis. The value of an acquired immunity to tuberculosis is well recognized. It is rather characteristic, but by no means constant, for granulomatous inflammation to be most frequently localized in those tissues and organs that anatomically contain the most macrophages or through which monocytes and lymphocytes migrate in largest numbers. Again tuberculosis provides pertinent examples and exceptions. There is, for example, an unusual and clinically confusing form of tuberculosis in which the lesions are almost entirely confined to the lymph nodes and other reticulo-

endothelial organs of the body; the lesions may be widely disseminated in them. Contrarily, tuberculosis of the skin can occur following direct inoculation. Many of the lesions of granulomatous inflammation acquire importance because of recrudescence or chronicity leading to cumulative injury; many become important because of a multiplicity of small, focal, tumorlike lesions that ultimately obstruct or preclude some body function.

INTERRELATION OF INFLAMMATION AND CHEMOTHERAPEUTIC AGENTS

The nature of the inflammatory reaction to bacteria may influence the chemotherapeutic approach to a disease. Again it is commonly observed that the panoply of the inflammatory process may be obviated by modern chemotherapy. Antimicrobial drugs may be bacteriostatic or bactericidal or both, but in order to be effective they must contact the bacteria in suitable concentration, whether the latter are intracellular or extracellular and whether in viable or necrotic tissue. Some agents, such as the sulfonamides, are essentially bacteriostatic and require the active participation of leukocytes and macrophages for their effectiveness. Other agents, such as penicillin, Terramycin, and tetracycline, are bactericidal and can kill susceptible bacteria without the participation of leukocytes and macrophages, although, of course, all agents will be aided by the ordinary natural and acquired defenses of the body. In the case of many acute bacterial infections in which the bacteria are largely present in the extracellular fluids, where they live and grow, the organisms can usually be rapidly eliminated by suitable antimicrobial drugs. Since no drug kills all bacteria at once but may require several hours or a few days to accomplish this, several days of therapy are necessary. Nevertheless, the inflammatory reaction as such is usually much minimized by such therapy and will subside before its usual course is run. It should be noted that the vascular and permeability effects of simple inflammation that serve to increase the flow of interstitial fluid in an area of inflammation also serve to bring blood-borne chemotherapeutic agents to the site. Indeed, in some cases

natural barriers to permeation may be partially broken. For example, the blood-brain barrier is normally impermeable to penicillin, but in the case of an acute meningitis the barrier may be partially broken and a small amount of penicillin and other nonpermeating substances may find their way into the cerebrospinal fluid. It should also be noted that agents that cannot penetrate cells in effective amounts cannot be expected to act on viable organisms within phagocytes or other cells. For example, the tubercle bacillus may survive and grow within macrophages, optimal chemotherapy requires the use of a drug that will reach these bacilli as well as those that are free in the interstitium or in necrotic tissue. Those inflammatory reactions in which extensive exudates, extensive tissue necrosis, or extensive areas of relatively avascular fibrous or cellular tissue develop may prove difficult to treat with antimicrobial drugs. While the increased permeability of vessels in areas of acute or subacute inflammation may allow the chemotherapeutic agent increased access to the area, the permeation of such agents into extensive, relatively avascular lesions, such as larger abscesses, empyemas, the vegetations of bacterial endocarditis, caseous foci in tuberculosis, impending arteriosclerotic gangrene of the lower limb, the diffuse interstitial fibrosis of extensive chronic pyelonephritis, the sequestra of chronic osteomyelitis, or the more avascular foci of neoplastic growth, is generally slow or ineffective in concentration. The surgical ablation of such lesions is usually warranted whenever practicable. It may be remarked that modern chemotherapeutic, antimicrobial agents have made great changes in therapy and now permit successful surgical procedures under conditions that were previously impossible, nevertheless, they in no way substitute for surgical competence or allow the relaxation of aseptic technique. In general, the more chronic a bacterial inflammatory process may be, the more unsatisfactory and prolonged is its treatment with antibiotics. Not only is it more difficult to bring antibiotics effectively to bear against the organisms in such lesions, but this difficulty makes more likely the evolution of resistant strains of bacteria that adapt to an environment containing the therapeutic agent.

It has been the purpose of this comment on the inflammatory reaction to emphasize some of the aspects of the inflammatory reactions to injury that may vary from site to site and from patient to patient. Obviously, the discussion has been fragmentary and important omissions have occurred, especially in relation to immunologic phenomena. However, it should be clear that the nature and course of an inflammatory reaction need not be constant, but that they may be modified by the constitution and status of the patient. Indeed, while present-day knowledge of the pathophysiology of inflammation is not great, nevertheless, it is often possible to recognize or anticipate certain deviations in the process in appropriate patients and to govern therapy accordingly.

REPAIR OF LESIONS

Following the demolition of injury and inflammation repair occurs. This may take place by regeneration in such a fashion that the tissue defect is occupied by the cells normal to the area in normal numbers, proportions, and arrangement and the region is entirely restored in structure and function. The blood is able to restore itself in this manner. Minor injuries to organs that involve the loss of scattered cells without damage to the reticulin and connective tissue scaffold in which they grow may heal with complete restitution. The repair of fractures of bone may be remarkably complete. More commonly, however, a defective area in an organ is replaced by connective tissue, largely fibrous tissue, that constitutes a scar. The repair process may combine both regeneration and replacement phenomena as in the healing of an incision of the skin.

Repair of Connective Tissue

Following an incision or wound of the skin and deeper structures of, say, the abdominal wall, the wound edges will gape. Approximation of the edges with sutures reduces the size of wound to be healed and will place structurally similar layers of the abdominal wall in apposition. The remaining small spaces between the edges of the wound are sealed by blood and plasma that exudes from damaged

and severed capillaries and is clotted in the presence of tissue juices from damaged cells. Following a period of vascular constriction that assists in hemostasis, vasodilation will occur and, if hemostasis is not adequate, further hemorrhage may occur. With the onset of hyperemia at the site of incision, a typical inflammatory process is established. In the case of a clean surgical incision with minimal cellular trauma, the inflammatory phenomena are also minimal. However, in wounds made by crude mechanical trauma with much cellular injury, the inflammatory response is marked. It will also be marked in infected wounds, in wounds contaminated by foreign material, or in wounds containing much dead tissue. Appreciable contamination of the wound will inhibit healing and, because of bacterial enzymes or as a result of inflammation, may bring about the solution of the clot material that initially unites the edges of the wound. Within 24-48 hours the fibrocytes that lie at the margins of a clean incision begin to multiply, and within 3-4 days from the time of injury they migrate into the clot material along fibrin threads. They are accompanied by macrophages and also by capillary buds that unite to form capillary arches. The clot is thus invaded by vascular connective tissue from all sides where it touches the host's tissue. The macrophages lyse the clot and remove it. Within 4-5 days the clot will have been replaced by vascular connective tissue growing in an organized manner. The process of organization joins the edges of the wound and replaces the previous fibrinous union by fibrous union. The wound rapidly gains tensile strength as the fibroblasts begin to assume the characteristics of fibrocytes and collagen is formed between them. A high level of strength is attained within 10 days. The tissue that unites the edges of the wound undergoes a subsequent maturation that may extend over several weeks or months. Much of the rich capillary supply to the newly organized tissue atrophies and only selected channels remain. The fibrous tissue develops a high content of collagen and a sparse content of elastic fibers. Many of the fibrocytes that were present disappear, a small number of macrophages remain as tissue histiocytes. A relatively avascular cicatrix results (see Fig. 5).

Repair of Surfaces

Repair at a body surface also involves *epithelial* or *mesothelial* regeneration. The epithelium of the skin will begin to proliferate as soon as it has a suitable surface over which to grow. In the healing of a clean approximated incision an exudate forms at the surface of the wound, clots, and dries to form a hard, relatively impervious, protective scab. With the organization and vascularization of the clot under the scab, a tissue develops that can support and nourish an epithelium. The epithelium at the immediate edges of the wound flattens and glides across the wound surface as a thin tongue beneath the scab by a mechanism called *thigmotaxis*. Mitotic activity occurs at a slight distance back from the immediate margin of the wound rather than at it. As the epithelium grows beneath the scab it loosens the scab so that it will fall off. Initially there may be some slight growth of epithelium on to the exterior surface of the scab at its periphery, but this is abortive. The epithelium grows across the wound as a covering, containing less than the normal number of cell layers, however, it matures to acquire them. It does not regenerate with complete restitution since appendages and rete pegs do not regrow.

Repair of Specialized Tissues

Other specialized tissues severed in the incision of the abdominal wall may or may not regenerate. *Adipose tissue* probably does not regenerate *sui generis* from adult or regressive fat cells but may grow rather by differentiation from connective tissue fibroblasts or reticuloendothelial cells. *Skeletal muscle* seldom shows mitotic activity, and while it may proliferate abortively to form syncytial, bulb-like terminations on the ends of severed fibers, continuity between severed fibers is only very rarely established. In the healing of a surgical incision of the abdomen it is not expected that any muscle continuity will be re-established. *Nerve fibers* that are severed degenerate distally and much of the free lipid that results from their disintegration is removed by macrophages during the subsequent several days. There occurs a similar, but much less extensive,

degeneration in the central stump of the nerve. Schwann cells proliferate along the course of the degenerated nerve, chiefly in relation to the peripheral fragment and, together with a lesser proliferation of Schwann cells from the central stump, bridge the gap between the severed portions. Axons begin to grow among the Schwann cells within a few days, and under favorable conditions can grow at the rate of 3-4 mm a day. The more accurately the proximal and distal stumps of the severed nerve are in apposition, the more prompt and successful will be the regeneration. The less accurate the apposition, the more disordered is the proliferation of Schwann cells at the point of severance and the greater is the possibility of the growth of an amputation neuroma. The *serosa of the peritoneal surface*, like the cutaneous epithelium, is brought into close apposition with itself when a surgical incision is closed. The remaining spaces in the wound are sealed with a blood or plasma clot. Since the peritoneal surfaces remain moist a dry scab does not form. The milieu of the peritoneal space is particularly suitable for the maintenance and growth of cells, and the single layer of mesothelial cells of the serosa can rapidly proliferate and glide across the wound and cover it. This may occur before organization of the clot has occurred. Excessive exudates of blood or plasma from the wound or excessive injury to the serosa may allow a clot to unite the peritoneum of the abdominal wall with that of some part of the gut before the mesothelium can cover the injuries. The subsequent organization of such connections results in fibrous adhesions. The adhesive bands are covered with mesothelium.

Repair of Larger Defects

The *healing of an open defect* in which the edges of the wound are not approximated differs somewhat from the repair of an incision such as described above. A craterlike defect must gradually fill with new connective tissues from its base and sides. The immediate surface of the wound presents a delicate layer of moist, clotlike exudate into which fibroblasts and capillaries grow. A new thin layer of exudate forms continuously at the advancing surface of organization. The manner in which

capillary arches form at the growth surface gives rise to a granular surface in which small elevations of fibroblastic tissue and exudate form at each point where there is a prominent leash of capillary vessels. When the surface of the wound is inspected it is found to consist of red, richly vascularized, moist tissue with a slightly granular surface. This is *granulation tissue*. The capillaries in it are subject to trauma and it can be easily made to bleed. If infection occurs, pus will be present in the surface exudate and the development of granulation tissue will be inhibited. With minor degrees of infection organization may still proceed; the infected surface of the wound is gradually reduced in extent and the defect is filled with granulation tissue. The epithelium at the edges of the wound lacks a suitable surface to grow across until the wound defect is filled. It proliferates only to a slight degree until this occurs. It then grows across the new surface. Occasionally it may grow down onto the surface of an incompletely filled defect but this is uncommon. In its essential biologic features the repair of a large open defect does not differ from that of an incision that has been approximated. In practice, however, the open wound requires much longer to heal because of the greater amount of tissue that must grow and because it is much more liable to contamination with bacteria or other substances that interfere with repair. Moreover, its surface may be so large that epithelium cannot cover it by growth from the periphery and skin grafts may be required. Granulation tissue covered by epidermis ceases to grow and the wound defect is normally repaired at a level similar to the adjacent undamaged tissue. However, occasionally this does not occur and an elevated mass of redundant connective tissue covered with epidermis grows at the site of an incision or wound. It is called a *keloid*. Certain individuals have a predisposition for this overgrowth of tissue in wound healing. The aberration is related to the constitution of the host rather than to the etiology of the wound.

Repair of Fractures of Bone

The *repair of fractures of bone* shares many of the features of simple wound healing. The fracture disrupts the blood channels within

and without the bone at the fracture site Hemorrhage and hematoma formation follow The periosteum may be partially elevated by blood. Repeated mechanical movement of the fracture site causes repeated vascular trauma Injury to the blood supply of the area will cause some ischemia which, together with mechanical trauma, will result in the death of some tissue. Both bony and soft tissues may be affected. The hematoma, together with any necrotic tissue, is removed by inflammatory reaction and replaced by organization It is not clear whether the connective tissue cells that organize the clot are fibroblasts that have the ability to differentiate into osteoblastic cells or whether there are specialized cells arising from the periosteum and endosteum that participate in the organization. In any case, the fracture site is united at first by clot and subsequently by a connective tissue mass This mass forms an elliptical swelling at the site of the fracture. It may be contained within the original periosteum or it may extend beyond it The structure is called a *provisional callus* It is highly vascular. The fibroblasts (osteoblasts?) contained in the callus soon begin to elaborate a basophilic fibrillar and amorphous ground substance between them in large quantities In this substance differentiation to form *cartilage* or *bone* occurs What determines the differentiation is unknown *Cartilage* tends to form more freely at the periphery of the callus or where there is much mechanical movement, but it also develops in an apparently random manner *Bone* develops through a stage in which the ground-substance matrix becomes eosinophilic and compact This material is called *osteoid* It is subsequently calcified. The fracture becomes united by a callus formed of connective tissue, cartilage, and bone The structure is preliminary and is subsequently modified by macrophages, by osteoclasts, and by bone formation until it is transformed into an architecture exactly resembling the normal bone The swollen callus is thus replaced by normal bone If surgical reduction of the fracture resulted in good alignment at the time the fracture was set, it may repair so well that no anatomic evidence of injury remains If, however, perfect alignment of the fractured ends could not be obtained, some residual distortion will remain

The factors that govern the remodelling of the callus and result in normal bone structure are unknown Soft tissue injuries adjacent to a fracture are repaired by fibrous scars.

Both *cartilage* and *tendon* repair by the formation of a clot in the defect caused by an injury Fibroblasts from the surrounding connective tissue grow into the clot. In the case of cartilage, a fibrocartilage is formed and it may subsequently undergo metaplasia to hyaline cartilage In a tendon, fibroblasts tend to orient longitudinally and to provide tough fibrous union between the severed ends

COMMENT ON REPAIR OF LESIONS

Regeneration

Regeneration is a remarkable phenomenon that may be organized to an incredible degree in many, but by no means all, primitive creatures In man, however, it is a rather limited event that seldom results in an organ-like or tissuelike product Regeneration must be preceded by certain regressive changes, including the completion of the local defense reactions, demolition of damaged cells and detritus, and dedifferentiation of the cells that will regenerate If the basic stromal pattern of the area is left intact and the parenchymal cells are of a sort that can regenerate, they will replace the demolished cells unit for unit Regeneration of this type is very common, and a constant cellular replacement goes on in the epithelia and parenchyma of the body The healing or regeneration observed in toxic myocarditis, e.g., diphtheria, in liver necrosis, e.g., viral hepatitis, or in acute nephrosis, e.g., shock, is often this type Regeneration in this fashion, however, is prevented if the stromal template of the cells is damaged The damaged stroma will itself regenerate by fibroblastic growth and the production of new extracellular fibers, but only in an architectural pattern inappropriate for the accommodation of the parenchyma. Nevertheless, reconstitution toward normal may occur, although it should now be regarded in the more general sense as repair rather than regeneration For example, after incision the repair of the duodenal mucosa may be remarkably detailed, but it is incomplete, since the muscularis does not regenerate The repair of a wound of the skin

surface involving destruction of cutaneous appendages is well organized but, again, restoration is incomplete

Scar Formation

Extensive injuries to parenchymatous organs with much destruction of stroma heal merely by the formation of a scar that partially replaces the lost tissue but is without its specific functions. This happens in many infarcts in parenchymatous organs and in organs such as the brain where regeneration of specialized cells is not possible. Where possible, the remainder of the parenchymal organ, or the contralateral organ, may undergo some degree of hypertrophy, a specialized form of restitution.

The formation of a scar in a gross tissue defect effects mechanical repair. In many situations the result is satisfactory. However, at some sites scar formation may interfere with function. For example, scar formation about the joints may limit movement, a scar about the lower eyelid may cause its eversion, adhesion scars in the peritoneum may obstruct the gut, and a scar in the brain may stimulate epilepsy. The surgical treatment of injuries at such sites is directed toward the prevention of gross scar formation, but if a scar has formed in such a manner as to interfere with function its revision may be necessary. One of the serious sequels to extensive infarction of the myocardium is the formation of large scars and fibrous aneurysms that may contribute to cardiac failure because they are noncontractile and because they stretch somewhat at each systolic impulse. In the absence of sufficient experimental data one can only speculate whether the surgical revision of large cardiac scars may be possible in the future and whether any benefit might be expected by the patient.

Influence of Blood Supply

The influence of the blood supply on both the demolition (inflammatory phase) that must precede regeneration and on the subsequent regeneration (repair phase) is of paramount importance. The metabolic requirements of inflammation and of repair are somewhat different, but both require an adequate blood supply

for their proper expression. It is not to be expected that an ischemic tissue that would not support an adequate inflammatory response will support a healing reaction. The dry, mummified tissues of a gangrenous extremity will not repair. If left, they will undergo autoamputation due to a healing process much like that occurring under a scab at its junction with viable tissue. Many examples of the general requirement for an adequate circulation may be given. It is surgically desirable to immobilize wounds or fractures until some tensile strength is gained, since the delicate capillary arches and sprouts at the advancing margin of organization are extremely fragile and rupture with the slightest force, but immobilization that increases circulatory stasis in the area is an adverse influence on healing. Patients with poor cardiorespiratory function will not heal as quickly as those with normal cardiac function. The stubborn refusal of varicose ulcers and decubitus ulcers to heal is attributable to local circulatory deficiency. The healing of myocardial infarcts may be somewhat delayed because the patient is suffering from some degree of cardiac failure as a consequence of the infarct itself. The sloughing of tightly placed sutures is partly an inflammatory process, partly an ischemic process, a wound apposed under extreme tension will be ischemic and will not heal. Tissues altered by severe radiation injury become ischemic and, due in part to their inadequate blood supply, do not heal well.

Influence of the Injurious Agent

It is obvious that regeneration and repair will require the cessation of the action of the etiologic agents of injury. Bacterial toxins and other agents will inhibit or destroy regenerating cells. The tubercles of tuberculosis and simple abscesses become encapsulated with fibrous tissue only after the infections have been arrested by the body's defenses. On the other hand, in some inflammatory reactions the irritant agent is present in such low concentration that it is capable of damaging only some of the cells. The surviving cells are more resistant and their regenerate daughter cells are also more resistant. Repair may then occur

that in adult life the effect of age on cell regeneration in wound healing is largely dependent on such a general factor as the blood supply to the area

Cortisone and pituitary adrenocorticotrophic hormone affect the processes of inflammation and healing. They have approximately similar effects. It is a matter of clinical experience that the hormones in sufficient dosage may reduce a patient's resistance to infection or the spread of infection and retard connective tissue repair. The mechanisms fundamental to the effects on the inflammatory process are not clearly established, but there is incomplete evidence that the hormones reduce the vascular responses of inflammation, retard and incomplete the cellular sequences of inflammation, inhibit the phagocytic ability of neutrophil leukocytes, and depress macrophages of hematogenous origin. At the same time healing is defective. Fibroblastic proliferation is reduced, perhaps due to arteriolar spasm and a diminution in the formation of new vessels, and connective tissue fiber formation is retarded. The wound does not fill with connective tissue nor does it gain tensile strength at the normal rate. The effects of cortisone and of ACTH on both the inflammatory defenses of the body and on the reparative proliferation of healing are of considerable therapeutic importance.

Many of the fundamental biologic phenomena related to healing are poorly understood. Some, such as nutrition, are under the general control of the surgeon. He can assure a high protein diet of good general nutritional quality or he can take steps to assure that excessive amounts of protein are not lost to the body from such lesions as extensive cutaneous burns or ulcerative colitis. Other fundamental phenomena such as age cannot be altered. There are, however, many obvious factors, often mechanical in nature, that have clinical application in the repair of wounds. The wound should be protected from the further action of the etiologic agent. Debris and dead tissue should be removed. Irritant chemicals may be removed by irrigation and bacteria by drainage or chemotherapeutic agents, and the wound may be protected from the subsequent entry of infective organisms. The size of the tissue defect to be repaired can

be reduced to as small a gap as possible by surgical revision and approximation. Certain tissue defects may be remedied by grafts or prostheses. Steps may be taken to assure that the blood supply is not further embarrassed by swelling of tissues beneath tight casts or by too much tension on sutures or tissues. Immobilization will prevent mechanical rending of delicate, newly formed tissues. Temporary or permanent re-epithelization may be obtained by grafting. The general mental and physical well-being of the patient may be sought.

The surgical principles of the treatment of wounds and similar defects are vital to the successful handling of such lesions. However, they are based on relatively subsidiary facets of the general biology of regeneration and repair. It may be hoped that further investigation will lead to more fundamental knowledge that may have application in the surgical treatment of disease, for our present knowledge is often inadequate to the demands that may, from time to time, be made upon it.

SYSTEMIC REACTIONS

The previous sections have considered the local reactions of inflammation and of repair and also the influence of the constitution and pathologic status of the patient on these local reactions. It is now necessary to comment briefly on the effect of the local reactions on the patient.

The complex but relatively constant nature of physiologic processes under changing environmental conditions has been known for many years. The ability of the body to maintain a relatively constant internal milieu in the presence of a moderately variable external environment has been expressed by the concept of *homeostasis*. The normal person has a considerable ability to adjust to variations in physical activity, temperature changes, alterations in atmospheric pressure and composition, food intake, etc. In the course of these adjustments a variety of physiologic states may be altered, and, while the individual may or may not be consciously uncomfortable, a new adjustment is soon accomplished and a new physiologic homeostatic state is established. The new homeostatic state is not a pathologic one; it cannot be described as a state of disease.

It is a state of adaptation to a changed environment. On the other hand, it is obvious that many changes in the environment do cause disease. In these circumstances either no homeostasis is possible in the continued presence of the environmental change, or, if homeostasis is possible, it can only occur together with the severe limitation or practical abolition of some physiologic function. There is a failure to adapt to the new environment and at the same time retain the functions and abilities that are normal to a state of health. The border line between successful adaptation and its failure is often difficult to establish.

Many environmental alterations elicit precise and specific physiologic responses. In these cases the stimulus and the response are intimately, sometimes uniquely, related. However, many other stimulus-response relationships lack this precise or unique quality. They are less specific. For example, a wide variety of events may be effective in stimulating the pituitary-adrenal gland axis. This hormone-mediated system has complex pathways of expression, but the general response to its stimulation is nevertheless approximately constant. Selye has recognized the general response to a variety of stimuli as something common to many disease states and largely independent of the special features of any given disease. The general response is said to represent the sum total of the nonspecific effects remaining for observation after the recognition of the specific responses peculiar to the particular disease that is being observed. Since this general response is often partially mediated by the hormones of the pituitary-adrenal axis, it frequently resembles the numerous physiologic effects that are based upon this axis. Selye regards the general response as adaptive.

Fever

Fever is one of the most common symptoms of disease. The temperature of the body is controlled from the hypothalamus where two incompletely separated centers maintain a balance between heat disposal and heat production so that the oral temperature approximates 98.6° F. Diurnal variations of 0.5°-2° F are common, and healthy individuals may occa-

sionally have oral body temperatures of as low as 96° F or as high as 103° F.

The production of heat derives from muscular activity such as exercise or shivering and from exothermic metabolic activity. An increase in body temperature of about 1° F. requires about 40 calories. The disposal of heat depends on the ability to transfer heat to the environment. It is mediated chiefly through the evaporation of sweat, the dilatation of surface blood vessels, and the respired air. If environmental temperature and humidity are too high, heat disposal mechanisms become ineffective and a fever of exogenous origin may be imposed on the body. This occurs in heat exhaustion or in artificial fever-cabinet therapy. Dehydration, especially in infants, may interfere with heat loss by diminishing sweating and peripheral vasodilatation. Damage to the heat disposal center in the hypothalamus may leave the ordinary activity of the heat production area unbalanced so that a neurogenic fever develops. Strenuous muscle exercise, especially in children, may cause transient fever. Hyperthyroidism may produce a sufficient increase in metabolic rate and muscular activity to cause a mild fever. Rarely, manic states may result in marked hyperpyrexia. Damage to the nerve tracts arising from the temperature control areas of the hypothalamus may render a patient poikilothermic.

The commonest examples of fever occur in infections and in diseases or injuries in which there is present a considerable amount of necrotic material. Many viral and bacterial infections cause fever, but others may be so localized that no systemic effect is noted. Severe sterile crushing injuries, internal hemorrhage, pulmonary or myocardial infarction or sterile neoplasms may all cause fever. The agents which cause the fever in these different examples are not known. It is possible to obtain from bacteria or from sterile inflammatory exudates substances called *pyrogens* that will elevate the body temperature. These substances are diverse and poorly characterized chemically. Their injection into the blood is not followed immediately by fever, but a latent period of considerable duration intervenes before the onset of pyrexia. Their mode of action on the

hypothalamus and medulla oblongata is entirely obscure. It does not appear to be mediated by the pituitary-adrenal gland axis. It is not established that the pyrogens that can be obtained from bacteria are responsible for the pyrexia of infections; indeed, it can be shown in a given case of infection that the pyrogens of the invading organisms do not account for more than a small fraction of the pyrexia that occurs. It is observed that if an individual is in a cool environment the development of fever will require vasoconstriction, cessation of sweating, and an increase in metabolic rate. However, if the individual is in a warm environment, the same degree of fever will be attained without any increase in metabolism. Apparently the hypothalamic centers can respond to the same pyrogenic stimulus in a different, adaptive manner according to the environmental circumstances.

Excessively elevated body temperatures are deleterious. The central nervous system does not well tolerate oral temperatures above 104°-105° F, and temperatures of 110° F, or sometimes considerably less may produce permanent cerebral injury. Insomnia is common even with mild fevers. Hyperpyrexia can cause hyperventilation and a degree of respiratory alkalosis that may be significant in infants and in some adult patients. The increased cardiac output that is usually required in hyperpyrexia may precipitate cardiac failure in patients whose cardiac reserve is small. Prolonged hyperpyrexia with its associated anorexia and elevation in metabolic rate causes protein wastage of significant amount and may occasionally cause ketosis. Liver failure may be precipitated in the patient who has a small hepatic reserve. Dehydration may both result from and further enhance hyperpyrexia.

With the exception of a few diseases, there is little evidence that hyperpyrexia promotes in any way the recovery of a patient from the infection, trauma, or infarction that may be causing fever. Nevertheless, a patient should respond to an appropriate stimulus by manifesting fever; the failure to respond appropriately is of serious prognostic import. Certain drugs have the ability to reduce fevers. Almost nothing is known about the mechanism of action of such antipyretic substances.

Leukocytosis and Leukopenia

Leukocytosis is a generalized reaction on the part of the hematopoietic organs that releases abnormal numbers of leukocytes into the circulating blood. It occurs in response to many stimuli. The ordinary fluctuations in the numbers of blood leukocytes under physiologic stimulation by muscular exercise, or to exposure to cold or heat, or in response to the pathologic stimuli of epileptiform seizures, pain, trauma, and similar stimuli are moderate. They consist of a leukocytosis that comprises chiefly neutrophil leukocytes and, after a short interval, the development of eosinopenia and slight lymphopenia. These fluctuations are similar to those produced by the injection of Adrenalin in the presence of an intact pituitary-adrenal gland axis. The reactions appear to be nonspecific and may be regarded as adaptive. The mechanisms of this form of leukocytosis are only partially understood. Adrenaline is released by the effective stimulus; adrenaline causes the pituitary to release ACTH which then causes the secretion of glucocorticoids from the adrenal glands. These hormones elicit leukocytosis in the pattern described.

The leukocytosis of various pathologic states occasionally resembles that described above, but it frequently differs so much that certain diseases are recognized to have particular, specific hematologic patterns or deviations. Overwhelming infections and chemicals, or irradiation that damage the hematopoietic organs, may cause leukopenia. Pyogenic bacteria and some nonpyogenic bacteria and viruses cause a marked neutrophilic leukocytosis. Other bacterial infections, such as typhoid fever or brucellosis, and many virus infections are accompanied by neutropenia and, frequently, also by lymphocytosis. Active tuberculosis stimulates lymphocytosis and monocytosis without affecting the number of circulating neutrophil leukocytes. Infectious mononucleosis stimulates profoundly the development of a mononuclear (lymphocytic) leukocytosis. Diseases of allergic nature are often accompanied by a marked increase in the number of eosinophil leukocytes circulating in the blood.

Almost nothing is known about the mechanisms concerned in the development of path-

ologic leukocytosis or leukopenia. Stimulation of the pituitary-adrenal gland axis would seem to be only one of several mechanisms that might operate in certain diseases. Nevertheless, the ability of the patient to react appropriately with the proper hematopoietic response is of the greatest importance. As in the case of fever, a failure to respond appropriately is of serious prognostic import.

Protein Metabolism

One of the common systemic reactions to injury is an increase in protein catabolism and the development of a transient period of negative nitrogen balance. With the onset of pain, fever, or a toxic state there is anorexia and an increased metabolic rate, protein is consumed faster than it is synthesized, and an excess of nitrogenous material is excreted in the urine. Confinement in bed for a sufficient time may lead to an appreciable disuse atrophy of skeletal muscle and protein loss.

Foci of tissue destruction caused by trauma, infarction, infection, or hemorrhage represent local areas of protein breakdown that contribute to systemic protein catabolism. The amount of protein that may be lost from hemorrhage to the exterior of the body or into the gastrointestinal tract may be large.

The protein loss from the surface of the colon during an active phase of ulcerative colitis may rapidly waste the patient and make him a poor operative risk. The amount of fluid and protein that may be dissipated from the weeping surfaces of extensive skin burns has been aptly called white hemorrhage. It is commonly accompanied by an excessive systemic protein catabolism. The cachexia of chronic infection, such as tuberculosis, or of carcinomatosis usually represents the combined effects of local tissue destruction, of anorexia, and of increased systemic protein catabolism.

The excessive systemic catabolism of protein that commonly follows upon injury to the organism does not appear to assist the recovery of the patient. Indeed, if it is severe, protein catabolism may make the patient cachectic, lower resistance, deplete wound healing, and render him more liable to secondary infection.

Chapter 3

Surgical Bacteriology and Chemotherapy

Gertrude G Kalz, MD, and Roger W Reed, MD

The purpose of this chapter is to give the student a general survey of the infections he is most likely to encounter in surgical practice. No attempt is made to give a complete list of all the infections which may occur or to discuss details of the bacteriologic technique or of the physiologic and other characters of the bacteria. The microbes will be discussed only in their relation to disease, and those characteristics only will be selected for notice which are essential for the understanding of the disease process and for a rational approach to treatment with either antiserums or modern chemotherapeutics. It is obviously impossible to make a strict division into surgical, medical, or other infections, but certain types are by their very nature treated by the surgeon, whereas others, although they may occur in a surgical patient, are by convention treated by the physician. No consideration will be given to the latter type of infection in this chapter.

Surgery owes a great debt to Lord Lister (1827-1912) who was the first to realize the importance of Pasteur's work to the field of surgery and who made an important contribution by applying the knowledge of his time to the operating room. Modern asepsis is only a further development of those first important concepts of antiseptics. Due consideration is given to the whole problem of sterilization and asepsis in the chapter on Surgical Technique.

HOST-PARASITE RELATIONSHIP

The host-parasite relationship involves certain structural and physiologic features of the bacteria which play a part in their adaptation to parasitism and the responses of the invaded host to the bacteria and their products. To evaluate the risks of infection in the operating field the surgeon should recognize the natural presence of certain kinds of bacteria in the various parts of the body, as well as possible outside sources. He must, therefore, be familiar with the means of preventing bacteria from entering wounds and of treating already established infections.

Pathogenicity is the broad term used to express the concerted action of a number of different characteristics which together enable microorganisms to cause disease. The type of disease is determined by the specific organism and its products, but the responses of the individual host give character of clinical importance to the disease. A variety of factors in the host are of great individual and collective importance and determine the degree of susceptibility and resistance to the infecting organism. Other features, like the site of localization or the organ or system invaded, are also of great significance. Certain bacteria have become adapted in certain localities and are accepted by the body without eliciting any reaction and cannot be completely eliminated from the region. Thus, the flora of the intestinal

tract, of the mucous membranes, and of the skin are examples of a well-balanced state between host and parasite, which is not only harmless but as in the case of the intestinal flora, may also be beneficial in synthesizing essential substances (vitamin K and some of the B complex). However, if some of these bacteria stray from their usual site into different tissues or organs, they may and do cause disease, although not all bacteria found in and about the body are capable of doing this. In order to cause infection, it is essential for a pathogenic organism to gain access to the body tissues and to be able to multiply there to a sufficient degree. The mechanism by which specific organisms cause disease varies, some cause their effects by powerful toxins and/or enzymes absorbed from a site of localization (diphtheria, tetanus), in some cases produced outside the body (botulism); others produce disease by active multiplication and local injury at the site or sites of invasion (Staphylococcus abscess, impetigo). A third group of bacteria may combine both modes of attack (gas gangrene), and yet others characteristically cause rapidly generalized infection and septicemias (typhoid, syphilis). Whether or not an infection remains localized or becomes generalized depends to some extent upon the bacterial species involved and upon the defense mechanism of the host, and various degrees and characters of infection may be seen in different cases due to the same species of bacteria (*Mycobacterium tuberculosis*, streptococci, *Bacillus anthracis*). Certain bacteria show selective localization in particular organs or tissues.

DEFENSE MECHANISM OF HOST

The response of the host to the microbe is manifold, depending in part on the particular species of microbe and in part on several factors in the host itself. We have said above that a prime factor in the establishment of an infection is the successful penetration by the bacteria or their products into the tissues of the host. The natural barriers which man possesses have to be broken down before access can be obtained. The normal self-sterilizing ability of healthy skin is a very successful line of defense, but even in the unbroken skin

there are weak spots which the enemy can attack, the hair follicles and the ducts of sebaceous glands represent such openings, may the bacteria, particularly *Staphylococcus*, may take advantage. Certain bacteria, such as *Pseudomonas* and *Leptospira*, are thought to be able to penetrate uninjured skin and mucous membranes. Wounds or other injuries to the skin provide a point of attack for a variety of bacteria. The portal of entry for the respiratory tract is the nose and nasopharynx. The mucous membranes, phagocytes, and the various secretions of the nose, pharynx, and the mouth provide a fairly effective barrier. Lysozyme, a bacteriolytic enzyme occurring in nasal secretions, tears, and other body secretions, may afford some protection against certain bacteria, and a certain degree of resistance may be provided by antibodies in the mucosal secretions. If any of these natural defenses are altered, the penetration of pathogenic bacteria is facilitated and infection of the upper respiratory tract will occur. The direct penetration of air-borne particles to the pulmonary alveoli is difficult, but the inspiration of infected materials and secretions may cause serious trouble.

Infections of the intestinal tract occur after the bacteria have passed several defense hurdles. In the mouth the saliva has an inhibitory action for some. The highly acid gastric juice will destroy another number of organisms, but many do pass this barrier in food which may act as a buffer or pass rapidly through the stomach in a fluid medium, and still others (*tubercle bacillus*) can survive for a certain length of time in the gastric juice. The type of flora found in the small and large intestine is determined by the anatomic structure, the secretions of the mucosa and accessory glands, and the dietary habits of the individual. Any upset in the normal physiologic conditions may permit the establishment of a number of intestinal pathogens.

In the healthy adult female the acid pH developing in the secretion and the type of epithelium of the vagina prevent fairly effectively the implantation of particular bacteria, e.g., coliforms, and may also restrict to some extent localization of gonococci, which can more easily establish themselves in the vagina of prepuberty children.

If bacteria penetrate these outer barriers, a second line of defense is provided by the process of phagocytosis and by "natural antibodies."

Phagocytosis represents an attempt of the body to rid itself of extrinsic matter and is highly successful with nonpathogenic organisms which reach the blood stream or tissues. If pathogenic organisms are introduced into the blood stream, the same clearing is less mobilized by the host, but the clearing is less successful because the ability to resist phagocytosis is a fairly common characteristic of virulent bacteria in general, and with some bacterial species it is the chief attribute of their pathogenicity. Even if pathogenic bacteria are taken up by phagocytic cells and a number of them are destroyed, the majority will escape after injuring or even killing the cells and start their process of multiplication or adaptation in various tissues. Most bacteria are not directly introduced into the blood stream but rather into some tissues or organs, and the immediate reaction of the body defenses is to localize and fix the injurious agent, the first clinical manifestation of the interaction between host and parasite is local inflammation. Polymorphonuclear leukocytes are mobilized from the blood stream and accumulate locally. After this initial wave of polymorphonuclear cells, which may be very brief in some infections, a second type of cells, the mononuclear macrophages, make their appearance and increase in numbers. Depending upon the bacterial species and its virulence, this mechanism is more or less effective. If it proves insufficient to destroy the majority of organisms, an invasion of lymph channels and blood vessels takes place and generalized infection will follow.

This cellular clearing mechanism is augmented and supported by components of the serum. It has been known for a long time that the serums of man and different animal species contain *antibodies* against various bacteria and red blood cells of other species. These antibodies which can render bacteria more susceptible to phagocytosis or can agglutinate or lyse microbes are connected with the serum globulin. They are often called "natural" or "nonspecific" or "physiologic" antibodies because they are present in the

serum of man or animals who are not known to have experienced previous infection with a given organism. The origin of these "natural" antibodies is still a hypothetical question, though they are more common and more abundant in the course of epidemics and are attributed by many to subclinical infections, by others to common antigens. The hemagglutinins that divide human blood into different blood groups are special examples of natural antibodies. The exact role of the natural antibodies in resistance to infection is not clearly established. Contrary to these antibacterial antibodies whose origin and exact value are still debatable, so-called "naturally" occurring antitoxins are almost certainly due to subclinical infection with the respective toxin-producing organisms, and they do confer antitoxic immunity of a specific type if present in sufficient amounts. This has been proved for diphtheria, tetanus, and scarlet fever. Of greater importance as defensive forces against infection are the antibodies which are formed in answer to a specific stimulus with the object of removing and neutralizing the bacterial or toxic substances or both. These antibodies are named "specific" or "immune" antibodies and they too are connected with the serum globulins. These antibodies are specific for the particular bacteria or their antigenic components, for instance, antibody produced against *Pneumococcus* Type I will only combine with Type I polysaccharide and is not effective against Type II, or antibody against *Haemophilus* Type B will only act on Type B and not on Types A, F, etc. Immune antibodies show a rising titer in recovery from an infection and can be transferred from man to man or animal to man and furnish protection against specific infection.

The formation and specificity of antibodies constitute one of the most fascinating subjects in biology. The site of formation of antibodies is still a controversial subject and cannot be discussed in this connection. Up to the relatively recent introduction of chemical agents into the treatment of infections, antibodies either actively produced or mainly passively introduced were the most important weapon in the fight against pathogenic microorganisms. But antibodies have definite limitations, they are effective only against bacteria

outside of tissue cells and cannot affect microbes inside the host cells. Antibody response has another shortcoming, namely, that on occasion it is accompanied by allergy. It is a controversial question whether "bacterial" allergy functions always to the disadvantage of the host. However, it is rather generally accepted that at least in certain infections (streptococcal) it would benefit the host if the allergic response could be suppressed and only the immune response retained.

In addition to the established value of serum antibodies, other components of the serum, namely complement and probably the *properdin system*, play a role in the defensive mechanism. Their exact interrelation and their relative values and functions are not entirely clear. In spite of available chemotherapeutic agents, antitoxins or antibacterial serums are still a valuable aid in the treatment of disease, and antitoxin is still pre-eminent in diphtheria and is essential in tetanus. Apart from the importance of antibodies as defensive forces, their appearance in response to infectious agents is of great significance in the diagnosis of a number of infectious diseases, as illustrated by the Widal reaction, brucella agglutination, and a series of other similar serologic tests based upon the demonstration of antibodies against specific microorganisms. The studies on the mechanism of antigen and antibody reactions have been tremendously stimulating and useful for decades and have led to a series of new concepts in immunity. The applications of highly specific antigen-antibody reactions have also resulted in the recognition of a variety of components in the bacterial cell which in turn has led to more exact identification of bacterial species, to new tools in the field of epidemiology, and to better appreciation of the processes of infection. An understanding of immunologic principles is of fundamental importance in every branch of medicine for diagnostic, preventive, and curative purposes.

The interaction between host and parasite in all its complexity determines the clinical course of an infection as well as the pathology of the lesions. The clinical signs and symptoms and the surgical treatment of various infectious processes are discussed in the appropriate chapters of this textbook. The de-

scription of tissue responses to bacterial invasion in general (inflammation, necrosis, fibrosis, etc.) or to certain specific microorganisms, e.g., tubercle bacillus, *Treponema pallidum*, fungi, is subject matter for pathology, and their discussion is omitted with the assumption that the student is thoroughly familiar with all the aspects. But, although redundant perhaps, a brief definition of terms which are commonly used in connection with infections is appended to prevent confusion of interpretation.

Abscess is a localized necrosis with a collection of pus confined by a wall of granulation tissue and may be acute or chronic. The furuncle or boil is a common form of abscess of the skin caused by *Staphylococcus pyogenes* which usually gains entrance through the hair follicle.

Cellulitis is a diffuse, often rapidly spreading inflammation of the subcutaneous tissues, frequently caused by the hemolytic streptococcus and involving the fascia. A serosanguineous exudate in which leukocytes are sparse is rather distinctive.

Bacteremia means the simple presence of bacteria in the blood stream, which may be transitory. This is a relatively frequent occurrence after tooth extraction or tonsillectomy without causing any serious symptoms.

Septicemia is a bacteremia with severe generalized symptoms, often accompanied by valvular lesions and other localizations.

Septicopyemia indicates a septicemia with abscess formation in various organs, usually initiated by infected emboli. These abscesses are known as "pyemic abscesses."

Toxemia signifies that the clinical signs and symptoms are due to a toxin rather than directly to bacterial multiplication. The best example of a toxemia is tetanus.

GENERAL ASPECTS OF THE TREATMENT OF INFECTIONS

Historic Introduction

The development in the treatment of infectious diseases can be divided roughly into three phases. The landmark in the first phase, which might be termed the *antitoxin-antisera phase*, was set by Roux and Martin (1894),

who immunized horses with diphtheria toxins and produced antitoxin. The extension and elaboration of this principle to other infections have been of immense value in the prevention and treatment of bacterial diseases. Behring and Wernicke (1892) actually treated for the first time a patient with diphtheria with serum from immunized animals. This marks the beginning of specific serum treatment. Infections in which treatment with antitoxin is still of prime importance will be discussed in the special part.

The second phase in the treatment of infections started with Ehrlich's work on chemotherapeutic agents (1904-1915), crowned by the discovery of "Compound 606" (1910), which as Salvarsan and all its related compounds has been the most effective weapon against syphilis for almost 35 years. The next important step in this phase was made with the introduction of Prontosil by Domagk (1935). The dramatic effect of Prontosil in streptococcal infections, particularly erysipelas, led to intensive investigations, and it was soon discovered by some French workers that the active principle of Prontosil was sulfanilamide. This compound was soon followed by more active and less toxic derivatives such as sulfapyridine, sulfathiazole, sulfadiazine, sulfamerazine, Gantrisin, and many others.

The usefulness of the sulfa drugs in surgery is somewhat limited by the fact that their activity is considerably decreased by the presence of pus and tissue debris in wounds. On the other hand, some sulfa drugs penetrate more freely into the spinal fluid than do antibiotics. They are therefore considered the drugs of choice in mild cases of meningococcal meningitis and are used in addition to an appropriate antibiotic in the treatment of other types of bacterial meningitis. Sulfa drugs are also employed in preference to antibiotics in the treatment of bacillary dysentery and some urinary tract infections.

The third and present phase in the treatment of infections, which logically is a continuation and part of the chemotherapeutic era, began with the discovery of penicillin by Fleming (1929) and its development for clinical application by Florey and Chain and many others (1940). This period of antibiotics, although of such recent origin, has

had the most stupendous effect on the whole field of medicine and allied sciences. The ever-increasing number of available antibiotic agents, all rather specific in their action, has put added importance on accurate diagnosis of bacterial infections for the proper choice and use of the most effective agent. It should be recognized and appreciated that our knowledge in this field is still limited and based to a large extent on empirical findings.

General Introduction

The exact mechanism by which the antibiotics exert their effect upon the microbial cells is not fully understood, although a certain amount of information is available. Our concepts and practices are therefore prone to changes, and statements as to choice of drugs, dosage, and route of application are only valid in the light of our present knowledge and experience. The choice of a particular antibiotic or of a combination of an antibiotic with other chemotherapeutic agents is dependent upon a number of factors such as the spectrum and relative toxicity, the available form for administration, concentrations obtainable, rate of diffusion, and excretion and stability. Other considerations are the type and severity of the infection and possible allergic reactions of the host.

The antimicrobial spectrum of an antibiotic refers to its relative selective activity against specific microorganisms. It has been realized recently that this expresses a quantitative rather than a qualitative characteristic. In the test tube most bacteria can be inhibited by practically all antibiotics, provided high enough concentrations are used. However, in the treatment of infections there are limits of obtainable concentrations in the body, and a definition of spectrum in this sense is still valid. As important, or even more important, from the practical point of view, are the variations in sensitivity from strain to strain within the same species or group of organisms. These variations are more pronounced in some bacterial species than in others. Antibiotics are either primarily bacteriostatic or bactericidal in their action although either characteristic is to some extent dependent upon the dosage and the microbe involved. It may be necessary to

use higher dosages and longer periods of treatment if antibiotics with mainly bacteriostatic activity are used in order to give the defense mechanisms of the body a better opportunity to eradicate the infection completely

Correlation Between in Vitro Findings and Clinical Effects

Sensitivity testing of isolated microorganisms has become a routine procedure in a diagnostic laboratory. It may well be asked how reliable and useful are such results with regard to the expected treatment response. To the alert reader the answer should already be obvious. By posing such a question it is implied that the correlation between the in vitro findings and the clinical effects is most certainly not absolute. The degree of correlation depends to some extent on the methods used for sensitivity testing, the microorganisms involved, the localization of the infection, and on a number of other factors in the host. Lacking a better foundation for the choice of a particular antibiotic, however, these tests have proved their practical value. It can be stated that, by and large, the effects in the body are better than those apparently indicated by the in vitro test, since humoral and cellular defensive forces enhance and aid the activity of the antibiotic. On the other hand, if the lesions are old, fibrotic, and poorly vascularized, the effect in the body may be considerably less than might be expected from in vitro sensitivity tests, since only small amounts of the antibiotic will actually reach the microorganisms. Furthermore, the designation of an organism as sensitive or resistant depends upon the methods and media used in different laboratories, and until standard methods and materials for testing of antibiotic sensitivities are developed, the results are not comparable. For all these and other reasons, the in vitro results should be used as a *qualitative* guide only for the choice and dosage of an antibiotic.

Development of Resistance

One of the most disturbing factors in antibiotic therapy is the development of *resistant strains*. This phenomenon has been observed

and studied by a great many investigators, and attempts have been made to counteract this limitation in the practical use of antibiotics. It is also one of the reasons for the constant search and development of new antibiotics.

Regarding the development of resistance of bacteria to antibiotics, there are two theories which have been proposed and which may in fact operate simultaneously. The *first theory* states that this phenomenon is due to spontaneous mutations which occur whether or not the antibiotic is present. When the antibiotic is present, it acts selectively to favor the survival of these resistant mutants. The significance of a mutation in every ninth or tenth generation becomes apparent only when the size of bacterial populations is considered, i.e., one ml of broth culture 24 hours old may contain up to 100,000,000 bacterial cells representing 30 generations. The number of bacteria present in the host at any time may be a very large multiple of this figure. Therefore enough mutants may appear to allow their survival and multiplication unless other factors such as body defenses can cope with them. An *alternate theory* states that resistance results from adaptation of organisms to sublethal concentrations of antibiotics. Eagle and his associates (1952) believe that the theories are not mutually exclusive. It is possible that slightly increased resistance following exposure to low concentrations of drugs may result from adaptation, while the highly resistant cells represent a spontaneous mutation.

However it develops, the resistance of bacteria, and in particular of staphylococci, to antibiotics is becoming a matter of great concern, particularly with respect to hospital-acquired infections. During the years 1946-1951, the number of hospital strains of staphylococci resistant to penicillin grew from 14% to about 70%. There has been no significant increase since then. During the same period, streptococci, pneumococci, and gonococci showed no such tendency. Staphylococci have shown a rapid development of resistance to streptomycin, chlortetracycline, and oxytetracycline but less to chloramphenicol due to its more restricted use. Since 25% or more of hospital staphylococci may be resistant to five or more antibiotics, the seriousness of the problem is immediately apparent. Resistant

staphylococci are not restricted to this continent but have been reported from all over the world where antibiotics of one type or another have been used for some time.

Various attempts have been made to counteract or circumvent the emergence of such resistant strains. One such approach has been to continue the search for new antibiotics effective against the multiple resistant strains. This search of course will have to be continued, since in time the staphylococci will become resistant to these new antibiotics as well. Another solution has been proposed by several authors, namely, to restrict the use of antibiotics to cases where there is a definite indication for their administration. As general restrictions of this nature are difficult to maintain, some hospitals have adopted a definite policy with regard to the use of one or two antibiotics. These antibiotics, still effective against staphylococci, are not used unless absolutely indicated in a particular case. The rationale of such decisions is based on the results of investigations which have clearly shown a marked difference in the incidence of resistant strains between hospital and outside patients. It is an established fact that cross-infections with resistant strains are common occurrences and responsible for the high incidence in hospitals. Spread occurs from patient to patient or via the hospital personnel acting as carriers. Reports from institutions where this policy has been carried out and maintained indicate that it is successful in preventing the emergence of resistant strains with respect to the chosen antibiotic or antibiotics.

In setting aside an antibiotic for restricted use, another problem must be kept in mind, the development of cross-resistance of an organism to more than one antibiotic. For example, in the tetracycline group of antibiotics, when an organism becomes resistant to, let us say, oxytetracycline, in most instances it also becomes resistant to chlortetracycline and to tetracycline itself although it may never have been exposed to the latter two antibiotics. The reason for this, of course, is the very close chemical similarity of the three drugs. Other instances of cross resistance have been observed and will be mentioned later. There fore, if at all possible, the new antibiotic

should be unrelated chemically to the antibiotics already in use. Other attempts to prevent emergence of resistant mutants have been made, such as combined treatment.

The Use of Antibiotic Combinations

There has been an increasing tendency over the past few years to use combinations of antibiotics in the treatment of infectious processes. Many claims have been made for the superiority of mixtures of two or more antibiotics over any one of the drugs used alone, and the increasing number of commercially premixed combinations has added considerably to their use. However, the choice of various combinations of antibiotics and chemotherapeutic agents must follow certain principles in order to achieve the objectives, and all too frequently these principles are ignored.

The studies of Jawetz and Gunnison (1953) and other investigators have shown that combinations of antibiotics may produce various effects both in vitro and in vivo. In brief, these effects may be (1) synergism, where the combined antimicrobial effect is much greater than that of mere addition, (2) additive, where the antibacterial activity of the combination is greater than that of either drug alone but neither more nor less than that obtained by doubling the concentration of either, (3) indifference, where there is neither increase nor decrease in action, and (4) antagonism, an effect less than that achieved with the more effective of the two drugs acting alone.

The evidence from in vitro experiments and from animal experiments has been summarized by Jawetz and Gunnison, who have listed currently used antibiotics in two groups: (1) primarily bactericidal, containing penicillin, streptomycin, bacitracin, neomycin, and (2) primarily bacteriostatic, containing chlortetracycline, oxytetracycline, tetracycline, chloramphenicol, erythromycin, carbomycin, and spiramycin. Mixtures of two or more members of Group I antibiotics frequently show synergism, sometimes indifference, but never antagonism. Members of Group II are neither synergistic nor antagonistic to each other, but simple additive effects are frequently observed. When

an antibiotic from Group I is combined with an antibiotic from Group II, the effect may be synergism, indifference, or antagonism. It is impossible to predict whether synergism or antagonism will occur with a given drug combination, since the outcome depends upon such complex factors as the relative concentration of the two antibiotics and the susceptibility or resistance of the bacterium to each individual drug. The result of a specific drug combination acting on a particular strain of the organism can only be determined by actual experiment and may not always be the same *in vivo* as *in vitro*.

For clinical purposes, *synergism* means a therapeutic effect obtained by the use of two or more drugs which could not be obtained with either drug alone in full therapeutic doses. On this basis there are very few types of infection where true synergism has been demonstrated clinically. These are in the treatment of enterococcic endocarditis with a combination of penicillin and streptomycin, of brucellosis with streptomycin and one of the tetracyclines or chloramphenicol, of certain staphylococcal infections with a combination of penicillin and chlortetracycline or streptomycin and oxytetracycline, and finally in the treatment of tuberculosis with paired combinations of streptomycin, isonicotinic acid hydrazide, and para-aminosalicylic acid (Dowling, 1957).

True clinical *antagonism* between paired antibiotics has been observed less frequently. Very definite ratios of two antibiotics must be present for antagonism to occur; for this reason such an effect is not often encountered clinically since the doses used are much larger than minimal effective doses. The best clinical example of antagonism is that reported by Lepper and Dowling (1951) when penicillin and chlortetracycline were used together in pneumococcic meningitis. Antagonism, however, may occur when the concentration of one or both antibiotics is at or below the minimal effective concentration. This has been demonstrated by Strom (1955) who, in the treatment of patients with scarlet fever, used either penicillin or chlortetracycline alone or the two combined. In summary, clinical evidence favoring the use of combinations of

antibiotics for the express purpose of obtaining better results than those obtained by using the most effective antibiotic alone can be justified only in the instances quoted above and in certain mixed infections.

Another reason given for the use of combinations is to obtain a good therapeutic result with nontoxic doses of two antibiotics which would otherwise require a toxic dose of either alone. Such combinations have been studied, particularly in the use of streptomycin and dihydrostreptomycin. It would appear from the recent studies of Wier and his associates (1956) that streptomycin alone is less likely to cause deafness than the use of the combination.

Still another reason for the use of antibiotic combinations is said to be the prevention of the appearance of resistant strains of the infecting organism. This theory has been applied practically for some years in the treatment of tuberculosis. Such combinations have also been utilized particularly in the treatment of staphylococcal infections. However, the usefulness of such a procedure is of limited value since the organism must be sensitive to both antibiotics before treatment is started, and in order to prevent the appearance of resistant strains, the two drugs should always be administered together in a given hospital and preferably throughout the entire country. The latter concept is hardly practicable, and it would appear that the prime use of such a scheme to delay the appearance of resistant strains is in the treatment of tuberculosis.

Combinations of antibiotics have been used in an attempt to combat the mixed flora of the gastrointestinal tract, thereby preventing the peritonitis that follows soilage from the intestine, or to treat mixed infections of the respiratory tract, the skin, and the urinary tract. Any one of the tetracyclines or chloramphenicol will prove as effective in lowering the bacterial count of the intestine as any of the recommended combinations of antibiotics.

There is also good evidence that the simultaneous use of polymyxin B and neomycin is more effective than either antibiotic alone and perhaps more effective than the tetracyclines or chloramphenicol. This combination has the

added advantage that hypersensitivity is unlikely to develop since absorption from the gastrointestinal tract may be kept to the minimum by proper dosage. In the actual treatment of peritonitis, the tetracyclines have been shown to be equal and perhaps superior to the combination of penicillin and streptomycin. If the latter are to be used, however, they should be administered separately, thus allowing a greater flexibility of dosage and route of administration than mixtures already prepared and dispensed.

Best results are obtained in the treatment of chronic bronchitis and bronchiectasis with one of the tetracyclines or chloramphenicol, and there is no evidence to date that these results can be improved with combinations of antibiotics. Lung abscess can best be treated with penicillin alone or a tetracycline alone. The use of nystatin in conjunction with a tetracycline is advocated by many to reduce the numbers of *Candida albicans* in the presence of large numbers of *C. albicans* in the intestinal tract, however, does not necessarily result in symptoms. If one is successful in suppressing *C. albicans*, some other organism which is not affected by the antibiotic used, such as *Proteus vulgaris* or resistant staphylococci, may become the predominant microorganism. It is also possible that the extensive use of nystatin in a hospital will cause the appearance of nystatin-resistant strains of *Candida* so that the drug will be useless when it is needed for therapeutic purposes.

The use of combinations of antibiotics has been recommended for the treatment of seriously ill patients before a bacteriologic diagnosis can be made. This practice is permissible if such therapy be given to those patients in whom the clinical diagnosis of an infection is reasonably certain and if the antibiotics used are selected to combat that particular infection. However, in the majority of cases, treatment prior to diagnosis is not necessary and in fact very often delays proper diagnosis and makes it more difficult. Also, under these circumstances, hypersensitivity to an antibiotic may occur, and if the proper combinations are not used, resistant forms of the organism may appear. If antibiotic therapy must

be used, an accurate clinical diagnosis is imperative, and this should be supported as quickly as possible by a dependable bacteriologic diagnosis together with in vitro sensitivity tests on the causative organism. In the rare cases where combined treatment is essential, one should bear in mind the possibility of antagonism when an antibiotic from Group I is combined with an antibiotic from Group II. In all cases each antibiotic should be given in full therapeutic doses.

Steroids and Antibiotics

There is no experimental or clinical evidence to suggest that cortisone or related compounds have any antimicrobial action. However, when used judiciously with antibiotics, they may at times be helpful and even lifesaving. Steroids probably have no place in the treatment of mild or moderately severe infections of bacterial origin. But evidence at the moment would indicate that a combination of steroids and antibiotics may be of considerable value in the treatment of overwhelming infections such as meningococcemia, in the treatment of selected cases of tuberculous meningitis, and in combating the toxemia and debility encountered in the early stages of severe typhoid fever and brucellosis. There is also good clinical evidence that the use of steroids together with antitoxin and penicillin is of real value in the treatment of patients suffering with severe tetanus. These, according to Herrell (1957), are the only bacterial diseases in which the steroids have proved of value, and their usefulness is not in any way connected with antibacterial activity. It should be mentioned that we know very little about the possible effect of cortisone and related compounds on phagocytosis and on antibody production. Experimental data indicate that while phagocytosis may not be interfered with, the ability of the cells of cortisone-treated animals to destroy the ingested organisms is greatly depressed. Other experimental evidence suggests that cortisone interferes with antibody production.

Complications of Antibiotic Treatment

A number of complications are frequently encountered following the use of antibiotics.

either alone or in combination. These are the appearance of secondary infections or superinfections due to organisms resistant to the antibiotic in use, the development of moniliasis, either local or general in nature, and the emergence of antibiotic-resistant strains of bacteria. One of the major problems resulting from the widespread use of antibiotics is the occurrence during or after treatment of secondary infections or superinfections caused either by bacteria resistant to the drug or by other microorganisms which, being opportunists, are able to take over due to the considerable reduction of the normal bacterial flora resulting from therapy. For example, massive doses of penicillin not only eliminate pneumococci in cases of pneumonia but also the majority of gram-positive bacteria from the upper respiratory tract. In the laboratory we can almost invariably tell when the patient has received penicillin by the predominance of coliform bacteria in the sputum. This disturbance in the balance of nature may sometimes result in definite symptoms when, for instance, the replacing organism is *Pseudomonas aeruginosa* or *Proteus vulgaris*.

One of the serious complications of antibiotic therapy is *staphylococcal enteritis*, which may occur following the use of any antibiotic but particularly after broad-spectrum antibiotics. In this case, staphylococci resistant to the antibiotic become the predominant intestinal organisms and, due to their toxins, are extremely irritating to the gastrointestinal mucosa. When the staphylococci are eliminated by the administration of an antibiotic to which they are sensitive, the symptoms of the enteritis disappear. Changes in bacterial flora of the respiratory or gastrointestinal tract which occur during antibiotic treatment do not always produce symptoms. If the replacing organism is a pathogen or potential pathogen, however, the result may be of great importance to the patient's well-being and also to the physician in determining his method of treatment.

One of the sequelae of antibiotic therapy is the outgrowth of the yeastlike fungus *Candida albicans*, normally a saprophytic organism present in small numbers in the upper respiratory tract or in the intestinal tract of some 15-20% of normal individuals. After the elimination of normal respiratory or in-

testinal flora, *C. albicans* becomes pathogenic and tends to invade the epithelium. In many cases rather annoying symptoms are produced which are characterized by moderate to severe diarrhea with perianal pruritus. In occasional cases, generalized and fatal systemic infections due to *C. albicans* have been described following antibiotic therapy. It is possible with the use of nystatin to eliminate *C. albicans* from the intestinal tract with almost complete relief of symptoms. However, all too frequently when the antibiotic is withdrawn *C. albicans* again appears in large numbers.

Fig 6.—Pseudomembranous enterocolitis due to antibiotic-resistant *Staphylococcus pyogenes*.

Most antibiotics in clinical use today have been so purified that the toxic side effects such as nausea, vomiting, and diarrhea have been reduced to an absolute minimum. These side effects can readily be arrested by withdrawing the antibiotic responsible for them. However, allergic or hypersensitivity reactions are commonly seen side effects of antibiotic therapy, due to the fact that practically all reactions to penicillin are of the allergic type and that

penicillin is the most frequently used antibiotic. Less serious hypersensitivity reactions are dermatitis, conjunctivitis, and stomatitis. These may occur in a sensitive individual from either local or systemic application. A wide variety of skin lesions may be seen following the use of antibiotics, chiefly penicillin and streptomycin. A serum sickness type of reaction consisting of fever and skin rash, with pain and swelling of multiple joints, is seen not uncommonly after administration of penicillin. Anaphylactic shock is the most serious of the penicillin reactions and may occasionally be fatal. Until recently the occurrence of this type of reaction was considered extremely rare. Lately, however, reports on fatal and nonfatal anaphylactic reactions to penicillin have been appearing with increasing frequency, no doubt because of the size of the population that is today sensitized to this antibiotic. Certain of the antibiotics, particularly neomycin and bacitracin, have a very low sensitizing index and as a general rule are used only for local applications. When administered systemically the possibility of a drug reaction on subsequent use is very low.

Indications for Antibiotic Therapy

There are at present 18 different antibiotics in common clinical use with others at the stage of experimental animal or clinical trial. If treatment is to be most effective, the appropriate antibiotic must be chosen quickly enough to prevent tissue damage or irreversible physiologic changes.

In the early days of the antibiotic era, the initiation of drug therapy without a bacteriologic diagnosis was perhaps permissible when only two or three antimicrobial agents were available. With the large number of drugs now available it is no longer feasible to follow this practice, particularly since some of the drugs though highly active are rather limited in scope. Ideally, of course, a bacteriologic diagnosis should be obtained before the initiation of antibiotic therapy. In the great majority of instances this policy is possible, but in extremely acute infections a good deal of clinical acumen is required in order to make shrewd bacteriologic inferences at the bedside. Therapy may be started but not until

adequate and proper specimens have been taken for bacteriologic diagnosis.

Antibiotics may be indicated for either the prevention or treatment of infections. The treatment of individual bacterial infections will be dealt with in a subsequent section. Prevention of streptococcal respiratory infections in persons who have had rheumatic fever or prevention of the bacteremias which may follow oral manipulations or surgery in patients with past or present rheumatic fever is considered desirable. Patients undergoing abdominal surgery involving possible perforation of the intestine should receive antibiotics preoperatively. Patients with diabetes, nephritis, or other complicating diseases which make them susceptible to infections should be prophylactically treated with antibiotics prior to surgery. Surgical procedures which must be carried out on infected or potentially infected sites should also be preceded by antibiotic prophylaxis. It should, however, be emphasized very strongly that all the modern "miracle" drugs do not permit the surgeon the slightest deviation from accepted standards of aseptic technique. They do make possible, in many instances, successful operations under conditions which formerly were followed by a high mortality rate. Skillful aseptic surgery remains of the utmost importance, and proper attention to nutrition, hydration, and all other supportive measures is most essential. The common practice of carrying out all surgical procedures under an "umbrella" of antibiotics is to be deplored.

A number of factors may influence the effectiveness of antibiotics *in vivo*, and these must be taken into consideration when determining the antibiotic to be used and the route of administration. One of the most important considerations is the concentration of antibiotic which can be expected in the environment of the organism. In the case of septicemia or of bacteremia, this is no problem. In general, the antibiotics available today are freely distributed through the body, but each has its own peculiarities which will be described. In fibrotic or necrotic lesions which are avascular or relatively so, it is very difficult for the antibiotic to diffuse to the center of the lesion in adequate concentrations. In such cases, surgical drainage combined with

local instillation of the antibiotic is the preferred treatment. For the treatment of systemic infections, the concentration of the chosen antibiotic should be maintained at least during successive recurring periods at 5-10 times the minimal inhibitory amount required *in vitro* for the particular organism

ANTIBIOTICS PRESENTLY USED

Penicillin diffuses after parenteral introduction into most tissues but does not penetrate freely into the bone marrow, the joints, body cavities, the intact central nervous tissue and not very readily into the spinal fluid, even in cases of meningitis, unless very high doses are used. In cases of empyema or other localized infections which are accessible to topical treatment, a combination of topical and systemic treatment is advisable. Antibiotics, in the form of aerosols either alone or in combination with intramuscular injections, may be the treatment of choice in certain types of upper respiratory infections. The large percentage of resistant strains of *Staphylococcus pyogenes* has put severe limitations on the usefulness of this antibiotic for the treatment of these infections.

Oral penicillin has proved to be effective against sensitive organisms, particularly for prophylaxis in patients with rheumatic fever. High dosage of oral penicillin has been necessitated by excessive destruction of the drug by acid in the gastrointestinal tract. Some time ago phenoxymethyl penicillin, an analogue of penicillin G, was described and was further investigated because of its unusual acid stability. This form of penicillin, which has come to be known as penicillin V, apparently remains insoluble in the acid pH of the stomach but is readily soluble and readily absorbed upon reaching the alkaline environment of the small intestine. Higher serum levels are obtained following oral administration with penicillin V than with an equal dosage of penicillin G. The absorption of benzathine penicillin V is much less affected by the simultaneous intake of food than is that of benzathine penicillin G. Hence penicillin V may be given with less regard to feeding and is in fact preferably given after meals. The administration of probenecid enhances serum levels of penicillin V in a

manner similar to its effect with penicillin G. It is now generally considered that penicillin V administered orally is more efficient because of its stability to gastric acids and because higher serum levels are obtained.

Streptomycin, like penicillin, is readily absorbed in the blood stream after intramuscular injection and is distributed to the various tissues. On the whole, so far as dosage and route of administration are concerned, very much the same rules apply as for penicillin. Streptomycin is active chiefly against gram-negative organisms, but some gram-positive species are also sensitive. The particular value of streptomycin is its activity against *Mycobacterium tuberculosis* and its synergistic effect with penicillin in the treatment of subacute bacterial endocarditis due to enterococci. If used over prolonged periods, damage to the auditory nerve may occur in a fairly large number of patients. Development of microbial resistance is a frequent phenomenon and may create treatment problems.

Chlortetracycline, oxytetracycline, and tetracycline are best discussed as a group as they show many common characteristics. All three have a broad antibacterial spectrum demonstrated by their activity against both gram-positive and gram-negative organisms and their activity against certain rickettsiae and large viruses. All three are rapidly absorbed when taken by mouth and are excreted in large quantities in the urine. All three are free from serious toxic properties, although nausea, vomiting, and diarrhea frequently interfere with the usage of the tetracyclines. Strains developing resistance to one agent usually show a marked cross-resistance to the other two analogues. The choice in any given infection will depend upon the sensitivity of the particular organism or organisms and upon possible sensitivities of the patient to one or the other of the antibiotics.

Chloromycetin (chloramphenicol) also belongs to the group of broad-spectrum antibiotics and, although chemically distinct, resembles in its activity and other properties the tetracycline derivatives. Gastrointestinal disturbances during Chloromycetin treatment have been reported but are not a major concern. Some consideration should be given to

TABLE I
THE PRACTICAL ANTIMICROBIAL SPECTRUM OF PRESENT ANTIBIOTICS

FUNGI	ACID-FAST BACILLI	GRAM- NEGATIVE BACTERIA	GRAM- POSITIVE BACTERIA	SPIRO- CHETES	RICKETTSIAE	VIRUSES		PROTOZOA
						LARGE	SMALL	
			Penicillin					
		Streptomycin						
		The Three Tetracyclines						
		Chloramphenicol						
		Neomycin						
		Polymyxin						
		Bacitracin						
		Tyrothricin						
Nystatin		Erythromycin						
		Carbomycin				Carbomycin		
	Cycloserine	Novobiocin						
Amphotericin B		Oleandomycin						
		Spiramycin						
		Kanamycin						

possible suppressive effects on the hematopoietic system by this drug if used over long periods.

Tyrothricin (combination of gramicidin and tyrocidine) is too toxic for systemic use but has certain advantages for topical application. It is effective mainly against gram-positive organisms.

Bacitracin has a spectrum similar to penicillin and has the advantage of not being inhibited by penicillinase, which may be an important point in the treatment of mixed infections due to gram-negative and gram-positive flora; it seems devoid of sensitizing properties. Its main value is in local application (surgical wound infections, furuncles, carbun-

cles, abscesses, and pyogenic dermatoses). The preparations now available for systemic treatment if given in the recommended dosage (20,000-25,000 units every 6-8 hours i.m.) and with a high fluid intake have no serious side effects and represent a valuable alternative to penicillin or other antibiotics, particularly in the treatment of resistant staphylococcal infections.

Polymyxin is active chiefly against gram-negative organisms. At the present time it is the most effective agent against *Pseudomonas aeruginosa*. Topical applications of polymyxin combined with bacitracin and neomycin are considered the treatment of choice in mixed bacterial infections of burns and wounds.

Parenteral use of polymyxin is limited to serious systemic pseudomonas infections, and proper attention must be given to its potential toxicity.

Neomycin has an antibacterial spectrum similar to that of polymyxin, although the latter is more effective against most pseudomonas strains and the former against proteus. Neomycin is restricted almost entirely to local treatment and is favored by many for preoperative intestinal preparation, as little or no absorption takes place. Because of its marked toxicity on parenteral dosage, this form of treatment is used only under special circumstances.

Erythromycin has an activity against gram-positive organisms similar to that of penicillin, and its greatest use is in the treatment of infections due to staphylococci, streptococci, and pneumococci. Gram-positive organisms resistant to all other antibiotics still may be attacked by this drug, and patients who are sensitive to other available antibiotics may be treated successfully with erythromycin. While it is somewhat less active than the tetracyclines against gram-negative organisms, it is a useful antibiotic to hold in reserve for the treatment of infections due to gram-negative cocci, particularly the gonococcus. It has some degree of activity against the large viruses, the rickettsiae, and some of the protozoa, although tetracyclines are more useful in these particular types of infections. One of the advantages of using erythromycin is that, due to its relative inactivity against gram-negative rods, it is perhaps less likely to alter the intestinal flora and to lead to complicating superinfections with *Candida*.

No cross-resistance has been demonstrated between erythromycin and penicillin, streptomycin, the tetracyclines, or chloramphenicol. However, cross-resistance occurs between erythromycin, carbomycin, and spiramycin. In man, toxic symptoms are not observed as a rule in the recommended dose of 300-500 mg q.6.h. Higher doses will cause gastric distress. Following oral administration erythromycin is readily absorbed, with a peak blood concentration occurring 2-4 hours subsequent to the administration of a single dose. Like penicillin, erythromycin does not readily pass

through the blood-brain barrier in the absence of inflammation. The drug will diffuse through the placenta. It diffuses readily into ascitic and pleural fluids. In the presence of normal liver function it is concentrated in the liver and excreted in the bile in active form. It is excreted constantly in the urine. Since erythromycin unprotected is partially destroyed in the upper gastrointestinal tract, specially coated tablets are used which protect the drug against gastric acids.

Carbomycin is principally active against gram-positive bacteria but has little or no effect against gram-negative bacteria. In addition it possesses some activity against rickettsiae and the large viruses. Its activity against gram-positive organisms is somewhat less than that of penicillin. Since no cross-resistance develops between carbomycin and penicillin, streptomycin, the tetracyclines, and chloramphenicol, this drug may be used in the treatment of infections due to gram-positive cocci resistant to these other antibiotics. However, cross-resistance develops between carbomycin, erythromycin, and spiramycin. Favorable clinical response has been obtained with carbomycin in acute infections caused by gram-positive cocci, but the results were less striking than those which would have been expected from penicillin. It may be said then that carbomycin is a poor substitute for penicillin in the treatment of infections due to gram-positive organisms, except in those cases where the organism is resistant to a number of other antibiotics. It would appear under such circumstances that erythromycin will produce a better result than carbomycin.

Oleandomycin, although only recently released for use, is not a new antibiotic. It appears to belong to the erythromycin-carbomycin-spiramycin group of antibiotics. Oleandomycin inhibits gram-positive organisms in vitro in a concentration of three gammas/ml. or less. It is active mainly against the gram-positive organisms and members of the *Neisseria*, *Hemophilus*, and *Brucella* groups, the rickettsiae, and to a lesser extent against the larger viruses and protozoa. There does not appear to be any cross-resistance with the common antibiotics, although about 20% of

the strains which become resistant to this drug *in vivo* show cross-resistance to erythromycin and spiramycin.

It has a low degree of toxicity and is well tolerated by man. It is not bound by serum proteins, and serum levels of 2.5 gammas/ml are obtained on a dosage of 2 Gm/day. Its greatest usefulness appears to be in the case of staphylococcal infections, where the organism is resistant to many other antibiotics.

Nystatin was discovered by Brown and Hazen in 1955, but its utility as an antifungal agent has not been thoroughly investigated until the past 2-3 years. The reason for the renewed interest in antifungal antibiotics such as nystatin has been discussed earlier. To treat patients with oral moniliasis, vaginal infection, and cutaneous involvement, the drug is used in several different forms, including topical ointments, solutions, powders, troches, vaginal suppositories, and vaginal gels. In all reported cases the results were good to excellent. The effects of nystatin in cases of deep mycotic infections have been equivocal, although *in vitro* the organisms appear to be sensitive. Nystatin probably should be administered along with antibacterial drugs to prevent the overgrowth of *Candida* in certain types of patients who are more likely to develop moniliasis, i.e., the debilitated patient, diabetics, and premature infants.

Novobiocin is mainly active against gram-positive cocci, although some gram-negative rods are also sensitive. *In vitro* antibacterial studies with novobiocin show that most strains of *Staphylococcus pyogenes* are inhibited by concentrations of 0.098-1.56 gammas/ml. Novobiocin sensitivity appears to bear no relation to susceptibility to other available antibiotics since freshly isolated strains of staphylococci resistant to penicillin, streptomycin, and the tetracyclines all proved sensitive to novobiocin *in vitro*. A high proportion of strains of *Proteus vulgaris* is inhibited in *vitro* by 8 gammas/ml or less. Other gram-negative organisms are not inhibited by novobiocin in concentrations obtainable with the recommended clinical dosage. The sodium salt of novobiocin is well tolerated in man, although a yellow discoloration of the plasma may appear a few hours after the first dose, which does not react to tests for bile. It would

appear that this yellow pigment is a metabolite formed from novobiocin.

Serum levels of 2-80 gammas/ml. are obtained and maintained on a dose of 250 mg. q 6 h or 500 mg. every 12 hours. There is considerable evidence to indicate that novobiocin is reversibly bound to serum albumin, thereby providing a reservoir of utilizable antibiotic. The drug does not diffuse through the normal blood-brain barrier.

The majority of staphylococcal and streptococcal infections treated with novobiocin respond very well to the doses mentioned. There is a very marked tendency on the part of staphylococci to become resistant to novobiocin *in vitro*. This has not been a problem in the treatment of patients.

Novobiocin is an extremely effective antibiotic for the treatment of resistant staphylococcal infections, and its careful use will make it a most valuable addition to the antibiotic family.

Cycloserine differs in chemical structure from any previously identified antibiotic. It has a low molecular weight, is highly diffusible, and has a broad antibacterial spectrum. It is said to have a synergistic effect *in vitro* with many other antibiotics. Although cycloserine is less effective *in vitro* than some of the well-known and currently used antibiotics, its activity *in vivo* is much higher than might be anticipated from *in vitro* tests. This, however, was not so in the case of the tubercle bacillus. Despite a promising degree of *in vitro* activity, little effect was demonstrable in experimental tuberculosis in mice. Several groups, however, have shown it to be an effective agent in the treatment of pulmonary tuberculosis in man, where it is used very cautiously because of its renal toxicity.

It has been suggested that this drug may be of considerable importance in helping to explain the mechanism of antibiotics, since there is some indication that it may be interfering with a common enzyme system or blocking a common metabolic pathway of a wide variety of microorganisms.

Spiramycin has been in use in Europe for more than a year but has only recently been introduced to this continent. It belongs to the same group of antibiotics as erythromycin and

carbomycin and shows cross-resistance with these two drugs. Spiramycin is well tolerated when administered orally, and no cases of staphylococcal enteritis or *Candida* infection have been reported following its use. It is particularly suitable for the treatment of infections due to gram-positive cocci which are resistant to penicillin and other commonly used antibiotics. It has been used successfully in treating staphylococcal enteritis resulting from the use of other antibiotics. The recommended oral dose of spiramycin is 3 Gm/day given in divided doses at 6- to 8-hour intervals. In severe cases this may be raised to 4-5 Gm/day. It has been suggested that spiramycin should be reserved for the treatment of patients who are sensitive to or cannot tolerate other antibiotics and those with infections due to organisms resistant to other antibiotics.

Amphotericin B is a relatively new antibiotic which has been shown to be very active against pathogenic fungi *in vitro*. No major toxicity has been observed on either oral or intravenous administration of this antibiotic. Therapeutic trials in cases of progressive histoplasmosis, cryptococcosis, and North American blastomycosis have given promising results, using intravenous administration, whereas the oral preparation has given rather doubtful results. This antibiotic appears worthy of more detailed clinical trials.

Kanamycin is one of the most recent antibiotics to be introduced for clinical use. It is active against a wide variety of gram-positive, gram-negative, and acid-fast organisms. There appears to be no cross-resistance, at least in the case of staphylococci, with penicillin, streptomycin, tetracycline, chloramphenicol, erythromycin, oleandomycin, and novobiocin. However, kanamycin and neomycin are almost completely cross-resistant, while kanamycin and streptomycin show incomplete cross-resistance. Staphylococci appear to develop resistance very slowly *in vitro*, while *Mycobacterium tuberculosis* does so more rapidly (Gourevitch et al., 1958).

Kanamycin is poorly absorbed after oral administration and at present only an intramuscular dosage form is available. Early clinical trials suggest occasional toxic manifesta-

tions, i.e., renal irritation, 8th nerve dysfunction, skin eruptions, and neutropenia. The recommended adult dose is 1-2 Gm/day in 2-4 equal amounts intramuscularly.

A number of antibiotics which are said to be active against certain types of tumor cells have been isolated in the past two years. None have reached the point at which they are ready for clinical trials, but they are being tested against experimental tumors in animals.

MICROORGANISMS OF IMPORTANCE IN SURGERY

In the following paragraphs the important pathogenic microorganisms in their relation to disease will be discussed. For the sake of uniformity the classification and terminology as given in Bergey's Manual (1948) will be followed, but long-established names in clinical use are given in brackets to avoid confusion, especially for those familiar with an accustomed terminology.

STAPHYLOCOCCUS PYOGENES

The term *Staphylococcus* for the species of medical interest has been in use for more than 60 years and will probably persist. Staphylococci are parasitic on the skin and mucous membranes and about 20% of people in some regions are nasal carriers. They are gram-positive, spherical cells and occur characteristically in clusters. *Staphylococcus* grows on all ordinary culture media. A useful provisional differentiation of the pathogenic from saprophytic strains is obtained by means of the "coagulase test." Pathogenic strains coagulate human or rabbit plasma (coagulase positive). Because of their wide distribution and their relative resistance to drying and heat, infections with staphylococcus are very frequent and will be encountered by the surgeons in one form or another almost daily.

Various clinical pictures are produced, ranging from mild superficial localized skin lesions to fulminating generalized infections. The ability of *Staphylococcus pyogenes* to cause disease is dependent on the toxins and enzymes produced by this organism, and the frequency and severity of the infections, as in most other diseases, depend on the relative susceptibility of the host and the defense

mechanism of the body. A soluble, filtrable, thermolabile exotoxin is produced by *Staph. pyogenes*. This exotoxin is antigenic and gives rise to an antitoxin. By treatment with formalin, an antigenic toxoid can be prepared and can be used to produce active antitoxin immunity. The exotoxin of *Staph. pyogenes* strains pathogenic for man contains a hemolysin for rabbit cells (alpha hemolysin), produces tissue necrosis, and is lethal for experimental animals.

Fig. 7.—Carbuncle in left scapular region showing characteristic multiple openings discharging pus

Whether the exotoxin is a single entity or whether these three reactions are caused by different fractions of the toxin is a question which still awaits an answer. Leukocidin, another toxic fraction of *Staph. pyogenes*, is of great importance for the establishment of infection because of its destructive action on leukocytes. This and coagulase are certainly partly responsible for the ease with which staphylococcus implantation occurs. Of the enzymes elaborated by *Staph. pyogenes*, mention has already been made of the coagulase which permits the differentiation of pathogenic from nonpathogenic strains. Fibrinolysin is another enzyme produced by staphylococcus for man to be confined to strains pathogenic for man. A mucolytic enzyme, hyaluronidase, is produced, which increases the permeability of connective tissue and assists the spread of the infection from the initial focus.

Staph. pyogenes is a good example of an organism which causes disease by active multiplication and toxic products. The clinical manifestations represent the sum total of both factors, and the clinical features of severe infections somewhat depend on which predominates, toxemia or bacteremia with pyemic abscesses. If the defense mechanism of the host plays its proper part after the initial invasion, the infection remains localized.

Staphylococcus infections occur in all age groups, but certain types are more common in children, e.g., osteomyelitis. *Staph. pyogenes* is probably the most common cause of wound infections, either alone or in combination with other pathogens. Primary staphylococcus infections range from the most superficial folliculitis through furuncles, carbuncles, and destructive osteomyelitis to fulminating septicopyemia. Many show a tendency to chronicity or persistence, particularly if the resistance mechanism is weakened by chronic diseases. Generalized spread may follow, either because of insufficient resistance or because the particular strain involved shows a high degree of invasiveness or toxin production. Thrombophlebitis and metastatic abscesses in practically any organ are a common sequence of generalized infection and occasion the severity of the clinical picture. The mortality rate in *Staph. pyogenes* septicemia in the pre-penicillin days was as high as 50-90%.

Staphylococcal infections are characterized by the formation of abundant pus. The pus is of a creamy consistency, slightly yellow in color, and consists mainly of polymorphonuclear leukocytes. Careful microscopic studies of stained films of the pus are often of help in assessing the state of resistance. Large numbers of engulfed cocci are a sign of good phagocytic response, whereas destroyed leukocytes with masses of cocci outside should be a warning that the infection may spread if effective measures are not taken. Sound surgical judgment has to decide the indication for operation and adequate drainage. Acute infections in well vascularized tissues will respond more readily to systemic treatment with appropriate antibiotics. Infections of the bone and joints, and older abscesses with fibrotic avascular surrounding tissue, require local as

well as systemic application after proper drainage in most instances; Staphylococcal empyema and brain abscesses have been treated successfully with systemic and topical use of antibiotics after drainage.

It has already been stated in the general discussion on chemotherapeutic agents that treatment of staphylococcal infections with antibiotics has become a major problem. Penicillin is still the drug of choice if the strain is sensitive, but only a small percentage of staphylococcal strains in hospital practice is susceptible to penicillin. It is no longer a question of using a "drug of choice" but of finding an antibiotic which will inhibit the strain in practically obtainable concentrations. Sensitivity testing of staphylococci is imperative if treatment with an antibiotic is indicated. The clinical importance of staphylococcal resistance can hardly be overemphasized. The vast number of reports on hospital staphylococcus infections is proof of the seriousness of this problem. Infections vary from relatively mild superficial to severe and even fatal types. Wound infections, urinary tract infections, and staphylococcal pneumonias are the most frequently encountered forms. Staphylococcal enterocolitis as a possible complication of antibiotic therapy has already been discussed. Various measures to combat these hospital infections, occasionally occurring in epidemics, have been suggested (Starkey, 1956). The difficulties of effective antibiotic treatment of these infections have focussed renewed attention on older forms of treatment. In addition to any effective antibiotic, the use of antitoxin is indicated in severe fulminating generalized infections when toxemia dominates the clinical picture, and may be lifesaving in less severe cases if the strain is highly resistant. Antitoxin should be administered intravenously as early as possible in such cases.

In chronic and recurrent staphylococcal infections, as well as in early stages of boils, staphylococcus toxoid has proved its value.

Antibiotics are often contraindicated in these cases unless the severity of a boil or carbuncle makes their use mandatory. The very chronicity of these infections, requiring the repeated use of antibiotics, leads to the de-

velopment of drug-fast strains with all the discussed consequences. The immunity produced by a course of toxoid is antitoxic and protects the tissues against the various destructive actions of the toxin. No general rules can be given as to how many courses may be necessary. Individuals vary considerably in their antitoxin response, and adequate titer has to be judged in every case by clinical improvement. With care and patience most gratifying results can be obtained in recurrent furunculosis and chronic osteomyelitis. In the rare condition of congenital aglobulinemia characterized by recurrent infections, the use of gamma globulin has proved of value in supporting the immune mechanisms.

STREPTOCOCCUS

The genus *Streptococcus* is of great importance in surgical practice and causes a wide variety of infections. Streptococci are gram-positive cocci which usually occur in chains of varying length and at times in pairs. A variety of species has long been recognized and many attempts at classification have been made. Differentiation according to changes produced on red blood cells has led to the terms hemolytic, viridans, and indifferens, which correspond respectively to *beta*, *alpha*, and *gamma* hemolysis. This caused overemphasis of hemolysis and the use of "hemolyticus" as a species epithet for which there is no justification. Actually there are five recognized species in the pyogenes group and two in the enterococcus group which are all hemolytic. Other classifications are based on the action of streptococci on a number of carbohydrates and other biologic reactions, and on these Sherman (1937) divided the aerobic streptococci into four sections: (1) the hemolytic pyogenic group, (2) the viridans group, (3) the lactic group, (4) the enterococcus group. A subdivision of the hemolytic streptococci on the basis of antigenic differences has been developed by Lancefield (1928) and some of these subgroups differentiate a single species, while others comprise two or more distinct species. Lancefield subgroup D comprises all the enterococci whether they are hemolytic or not. No completely satisfactory classification has as yet been found for the viridans group.

and the anaerobic species. The growth requirements of streptococci vary for the various species, but blood agar usually provides a reasonably satisfactory medium for the isolation and characteristic colony production.

The variety of clinical signs and symptoms produced by streptococcal infections has led to the intensive search for the factors responsible for the differences both in the bacterial cell and in the host. Streptococci are widely distributed among man, animals, and probably plants. Some species are harbored as commensals in the human mouth and throat. Most species may survive at least for several weeks in clothing, bedding, and food. Milk is a favorable medium, and milk-borne streptococcal epidemics are not uncommon. Crowding as in schools, barracks, hospital wards, etc., increases the incidence of streptococcal infections. The two dread diseases of the surgeon, and obstetrician, erysipelas and puerperal fever, are fortunately more of historic interest today, but the efforts of men like Holmes, Semmelweis, Billroth, Lister, and many others should not be forgotten.

Extensive studies have led to the recognition of a number of components in the streptococcal cell which have contributed to our understanding of the disease processes. The serologic classification of many aerobic streptococci depends on differences of a carbohydrate "C" substance, and although it has no relationship to virulence, it provides the grouping of streptococci as already pointed out. The vast majority of human infections seem to be caused by Group A streptococci, although other groups occasionally cause disease. The groups can be further divided into types, and within Group A, for instance, at least 40 specific types have been identified. The type-specific antigen is a protein "M" substance, and antibodies against it confer type-specific protection. The amount of "M" substance produced by a given strain is partly responsible for virulence. Type-specific antigens in other groups are either proteins or polysaccharides. Two other fractions occur in the cells, "T" and "P" substances, which are not known to have any bearing on the virulence or pathogenicity of the strain. A number of other substances elaborated by streptococci have to be discussed briefly because they are essential for the un-

derstanding of the pathologic features of streptococcal infections. The erythrogenic toxin, produced by streptococci, particularly of Group A, some of Groups C and G, is held responsible for the rash in scarlet fever. Immunity after scarlet fever is antitoxic, and only the erythrogenic toxin is neutralized, but no protective effect against the bacterial cell is provided. At least five immunologically distinct toxins are known which may explain the occurrence of an occasional second or even third attack of scarlet fever.

Most Group A streptococci produce two different kinds of hemolysins, O and S, and the latter is pathogenic for laboratory animals. Antibodies against streptolysin O can be demonstrated following infections with streptococci producing streptolysin O and may persist for years. The part this O lysin plays in the pathogenicity of the strain is not known, but streptolysin O antibodies have been investigated for epidemiologic studies.

Two enzymes, or pro-enzymes, produced by many strains of streptococci of Groups A, C, and G, namely, streptokinase (fibrinolysin) and proteinase, are both antigenic, but their relation to the lesions produced in infection is still obscure. Some strains elaborate hyaluronidase, an enzyme which is capable of breaking down hyaluronic acid, which forms the intercellular ground substance of connective tissue and cartilage. This enzyme was thought to be responsible for the invasiveness of streptococci, but many highly pathogenic strains do not produce it; furthermore, many highly virulent streptococci are encapsulated and the capsule is formed mainly by hyaluronic acid.

Summarizing, we can only state at present that pathogenicity is associated with the "M" substance and the erythrogenic toxin. How much the other discussed components contribute to the virulence of a given strain remains to be proved.

It is of interest to realize that some of the substances elaborated by streptococci are now used therapeutically by the surgeon—streptokinase and streptodornase.

Hardly any other bacterial species is capable of causing so many diverse pathologic and clinical pictures as streptococci. Streptococci

commonly enter through accidental wounds which may be quite small and hardly more than scratches. The response to this invasion depends on the strain and the susceptibility of the host. We have to differentiate between infections caused by the various groups of aerobic streptococci and the microaerophilic and the anaerobic streptococci.

The following clinical manifestations are caused in the vast majority of cases by *Streptococcus pyogenes* Lancefield Group A, more rarely by Group C, and very occasionally by Group G.

1 *Erysipelas*. The clinical picture is characterized by a *brawny-red* induration of the skin. The margin of the erythema is raised and irregular. Occasionally small blisters are formed on the surface, from which *Str. pyogenes* can be isolated. If unchecked by treatment and in a patient without resistance, erysipelas can spread rapidly. Under such conditions, signs and symptoms of toxemia develop. Histologically the main feature of the lesion is intense inflammation of the superficial lymphatics which are filled with polymorphonuclear leukocytes, fibrin, and bacteria.

2 *Lymphangitis, lymphadenitis, cellulitis, and septicemia*. From a small puncture wound a red streak along the lymph vessel rapidly develops, the regional lymph nodes become tender and enlarged, and softening and supuration may follow. If spread is not checked bacteremia and septicemia may follow, usually originating from a thrombophlebitis or directly from the lymphatics. Chills and high fever are the clinical signs of blood stream invasion, and other signs and symptoms may develop, depending on the site or sites where infected emboli may be lodged. These may give rise to abscesses in the spleen, kidney, or brain or to purulent arthritis, pleuritis, pericarditis, peritonitis, or meningitis. This sequence of events may occur irrespective of the primary portal of entry. The upper respiratory tract is a frequent primary site of invasion and of major interest to the otolaryngologist. Pharyngitis, follicular tonsillitis, peritonsillar abscesses (quinsy), retropharyngeal abscesses, and the now rare condition of Ludwig's angina are all caused by *Str. pyogenes*. From the nasopharynx the streptococci may pass through the Eustachian tube to the middle

ear and mastoid and to the large cerebral sinuses. Any of these may in turn lead to generalized infection. The involvement of the regional lymph nodes is very characteristic of streptococcal infection.

Recognition of the cause and proper counteraction have almost eliminated puerperal fever, a once very prevalent type of streptococcal infection, and if infection post partum does occur immediate treatment will in most instances prevent serious sequelae.

Infections with *Str. pyogenes* have fortunately lost much of their serious implication for the patient. *Surgical drainage, wound débridement, and chemotherapy*, either in the form of sulfonamides or in more serious cases in combination with penicillin or other antibiotics, will in most cases prevent spread and induce recovery.

Dosage and mode of application have to be adjusted to the individual case and should follow the principles as outlined in the general discussion. For superficial wound infections or infections of burns where local treatment may be a more rational form, topical application of bacitracin may be preferable to penicillin because of lack of sensitization.

The *viridans* group of streptococci is of much less concern in surgical practice. They probably play a role in infections of the gall bladder and apical abscesses of teeth and are the cause of a certain number of urinary tract infections. Pathogenicity of the lactic group for man has never been established. In the treatment of any infection due to a member of the viridans group of streptococci, it should be kept in mind that these organisms are less sensitive to penicillin and a higher dosage is required.

Subacute bacterial endocarditis is considered a medical problem, with the exception of those cases where the vegetations are situated in a patent ductus arteriosus. Ligature or division and suture of the ductus may be indicated. Intensive antibiotic treatment before and after operation will aid this procedure.

The last group of the aerobic streptococci comprises four species, commonly called *enterococci* or *fecal streptococci*, and all four species belong serologically to Lancefield Group D. Enterococci, as the name implies,

form part of the flora of the intestines, particularly the colon. Their main importance is in infection of the peritoneum and the urinary tract and in subacute bacterial endocarditis. Either alone, or more often with the colon bacillus, they are found in appendiceal abscesses, localized or diffuse peritonitis, and following inflammatory processes or injuries to the terminal ileum, appendix, or colon. In the urinary tract they cause cystitis, pyelitis, and pyelonephritis. Invasion of the blood stream is rare but does occur, particularly following surgery on the infected kidney. Combined penicillin-streptomycin is the accepted treatment in subacute bacterial endocarditis.

Several species of *anaerobic streptococci* are of clinical importance. They can be isolated from the mouth, intestines, and vagina of apparently healthy persons; relatively little is known about their antigenic structure, and their pathogenicity for laboratory animals seems to vary widely. Their presence is often suggested by a foul odor and gas formation. Anaerobic streptococci are a frequent source of post-partum infection, either of a localized nature, as endometritis, or giving rise to generalized infections in which they can be isolated from the blood stream. Anaerobic streptococci are also often found in lung abscesses, usually in combination with other organisms,

FIG. 8 Typical undermining ulceration (Meleney) due to a microaerophilic hemolytic streptococcus

due to enterococci. Sulfadiazine and other sulfa drugs are used successfully in the treatment of urinary tract infections.

Meleney (1935) described a peculiar spreading, burrowing, undermining ulceration of the skin caused by a microaerophilic hemolytic streptococcus. Treatment with zinc peroxide has been highly effective if the method as outlined by Meleney is carefully followed. "Progressive postoperative bacterial synergistic gangrene" is due to a nonhemolytic microaerophilic streptococcus (*Str. evolutus*) in synergism with a *Staph. pyogenes* according to Meleney (1949).

more rarely in mastoiditis and brain abscesses. Traumatic wounds with crushed tissues favor the growth of this group. Abscesses adjacent to the intestinal tract (perirectal, pilonidal cysts) are sometimes caused by anaerobic species, which can also be found in mixed cultures in appendiceal abscesses and peritonitis. The pus and discharge are often, but not always, foul smelling. Most anaerobic strains of streptococci are sensitive to penicillin, but as they often occur in mixed infections, combined treatment with penicillin and streptomycin or one of the broad spectrum antibiotics may be a more adequate form of

therapy. Drainage of any accessible accumulation of pus and removal of necrotic or gangrenous tissue are essential and, depending on the severity of the infection and the tissues or organs involved, local and systemic treatment with the chosen chemotherapeutic agents may be indicated

DIPLOCOCCUS PNEUMONIAE (PNEUMOCOCCUS)

The pneumococcus is a gram-positive, ovoid coccus with an easily demonstrable capsule. The pneumococci are arranged in pairs and short chains. They can be grown fairly readily, and on blood agar the colonies in aerobic culture produce a zone of greening. Bile or bile salts bring about rapid autolysis of the pneumococci, and turbid suspensions are cleared in a short time on incubation at 37° C. This simple test can be used to differentiate pneumococci from the viridans group of streptococci, the only organisms with which they could be confused. Pneumococci occur in the upper respiratory tract and cause infections mainly of the lungs, the accessory sinuses, middle ear, and meninges. Rarer but of greater importance to the general surgeon are pneumococcal peritonitis, metastatic purulent arthritis, and empyema. As mentioned above, a characteristic of the pneumococcus is the capsule, and on the basis of differences in immunochemical structure of the capsular polysaccharide, pneumococci can be divided into at least 75 types. These capsular polysaccharides are antigenic, and type-specific antibodies are protective. The capsule is an essential attribute for the pathogenicity or virulence of pneumococci by increasing the resistance of the bacterial cell to phagocytosis (Avery, 1932) (Wood, et al, 1946). No toxins in the accepted sense have been demonstrated. The physical appearance of pneumococcal pus differs from other pus by its high content of fibrin and its extremely tenacious character which is of practical importance because it hinders proper drainage and penetration of therapeutic agents. Streptodornase is used to liquefy pneumococcal pus in order to facilitate the access of drugs to the organisms.

The sulfa drugs and antibiotics have considerably lowered the mortality rate of pneumococcal infections. This is of great impor-

tance to the surgeon, as postoperative pneumonia was one of the serious consequences of many surgical interventions. Empyema, too, has become a relatively rare disease, and if it occurs can usually be well managed. The pus should be aspirated and replaced by local instillation of an antibiotic (penicillin) supplemented by systemic treatment if necessary. The same approach is successful in the management of pneumococcal arthritis.

Pneumococcal meningitis remains a serious problem; primary foci, usually in the sinuses or mastoid, must be eliminated. Development of resistance of pneumococci to penicillin is a rare occurrence, but the possibility must be kept in mind, and if clinical improvement does not follow an ordinarily sufficient dosage of penicillin, the sensitivity of the strain should be tested. Significant spinal fluid concentrations are obtained following standard dosage of tetracyclines and these antibiotics are used in meningeal infections. As pneumococci are carried by many people in the nasopharynx and cause a large number of sinus infections, the surgeon must be alert to the danger of pneumococcal meningitis in all cases of skull fractures.

ENTEROBACTERIACEAE

This family contains a number of species; some live in the intestinal tract as commensals and others are obligatory parasites. All species are gram-negative rods and many show active motility by means of flagellae. All members of the family can be grown on ordinary culture media and ferment a variety of carbohydrates with the production of acid or acid and gas which, with other metabolic characters, are used to differentiate the various species. The lactose-fermenting genera are *Escherichia*, *Aerobacter*, and *Klebsiella*, and the first two are often referred to as the colon-aerogenes group. *Escherichia* can be divided into three species, *E. coli*, *E. freundii*, and *E. intermedium*, but for the sake of simplicity we shall use the collective term *E. coli* for the three species. *E. coli* is an inhabitant of the intestinal tract of man and animals and as such is not only harmless but, as already mentioned, is also useful in synthesizing certain vitamins (Johannson and Sarles, 1949). This has certain practical implications for the surgeon. The preparation of

the intestinal tract with sulfonamides and antibiotics before major surgical procedures on the colon has been adopted as a routine procedure and the decrease in bacterial flora, if protracted, may lead to vitamin deficiencies. This fact has been recognized and joint administration of vitamins and antibiotics is recommended.

The infections caused by *E. coli* are usually of a localized nature involving organs anatomically related to the intestines. *E. coli* is the most common cause of cystitis, pyelitis, and pyelonephritis. Of greater interest to the general surgeon are the infections in the abdominal cavity, peritonitis, and cholecystitis. In appendiceal abscess, *E. coli* can be found in combination with a variety of other organisms; it certainly is not the primary cause of appendicitis. In peritonitis following perforation of some part of the intestine, *E. coli* is often the only or the predominating organism. In infants invasion of the blood stream followed by metastatic abscesses, particularly in the brain, is not a rarity. *E. coli* also plays a part, often in combination with other organisms (staphylococcus and streptococcus), in burns or in postoperative infections of abdominal wounds. The purulent discharge from *E. coli* infections often has a foul odor.

Removal of the primary focus of infection (appendix, gall bladder) and effective drainage of abscesses are as always the important steps. In the choice of an antibiotic, consideration must be given to the sensitivity of the strain. In the treatment of urinary tract infections, attention should be paid to any anatomic malformations or other occlusions which prevent free drainage and penetration, otherwise even the most effective antibiotic will only produce temporary relief. The *Aerobacter* of different species produce, on the whole, the same type of infections as *E. coli*.

Klebsiella pneumoniae is a gram-negative, nonmotile rod. It grows well on ordinary nutrient media with large mucoid colonies. A striking morphologic character is the capsule containing a type-specific polysaccharide. and Julianelle (1926) described three antigenic types, A, B, and C, and a heterogeneous Group X. Types A and B are much more frequently found than type C and seem to be

more highly pathogenic. Friedländer's bacillus appears to live in the upper respiratory tract of man and has also been isolated from feces in healthy persons. Surgical infections caused by Friedländer's bacillus are empyema, bronchietasis, sinusitis, occasionally appendiceal abscess, cystitis, and pyelonephritis. Brain abscesses and generalized septicemia with metastatic abscesses are rare complications. The exudates in Friedländer infections, unless frankly purulent, are highly viscous, due to the large amount of capsular material. Sulfadiazine and streptomycin have sometimes shown good results in the treatment of *Klebsiella* infections and the broad-spectrum antibiotics have been used successfully in small groups of cases. In an individual case the choice of drug is best made on the basis of sensitivity tests.

Salmonella typhi (typhoid bacillus) is a gram-negative motile bacillus, the causative agent of typhoid fever. It concerns the surgeon both during the active disease and in connection with lesions occurring years after the initial infection. The typhoid bacillus grows readily. It can be isolated from the blood of the patient during the acute stage (first week and beginning of second week) and from the urine and stool from the end of the first week on. Antibodies against various fractions of the bacillus appear in the blood, usually in the third week, and may persist for several years after recovery, conferring a certain degree of immunity. The Widal reaction is based on the demonstration of these antibodies by agglutination of bacterial suspensions. The widespread artificial immunization against typhoid fever has somewhat impaired the diagnostic significance of the Widal test and the evaluation of positive results has to be based on at least two successive tests at a few days' interval. Endotoxins which are liberated by autolysis of the bacilli are highly toxic and considered responsible for the clinical findings which are chills, fever, malaise, and headache.

The surgical lesions during the active stage of typhoid fever are orchitis, epididymitis, perichondritis, and perforation of the intestinal ulcers with local or generalized peritonitis. Meningitis and empyema may also occur during the acute stage. It must be kept in mind that typhoid fever is a systemic disease and

bacteremia is the main feature. Localization of organisms in practically any organ may result, although the gall bladder, kidneys, and bones are most commonly affected.

Chronic cholecystitis with or without acute exacerbations, often with formation of stones, is frequently due to the typhoid bacillus. Suppurative periostitis of the tibia, ribs, or vertebrae may be a late sequel. The diagnosis can be established only by the isolation of *Sal. typhi*. A few other members of the large *Salmonella* group may give rise to a similar clinical picture. Chloromycetin is the treatment of choice for typhoid fever. The results in a large series of cases have been very gratifying; the hopes, however, that the carrier state may be prevented or eradicated have not materialized.

Only one other group of lactose-negative organisms of the *Enterobacteriaceae* family is of interest to the surgeon: *Proteus*. The members of this group are gram negative, motile bacilli, which are widely distributed in nature, sewage, and manure, and are frequently found in small numbers in the feces. Members of the *proteus* group are frequently the cause of urinary tract infections, which can be extremely severe and lead to invasion of the blood stream, particularly following renal surgery. As one of the intestinal inhabitants, it is sometimes found in combination with other organisms in any infection of the abdominal cavity. The chief importance of the *proteus* group is as secondary invaders in wounds, middle ear diseases, ulcerations, and burns, particularly of the lower extremities (fecal contamination). Some members of the *proteus* group are highly proteolytic, and any attempt at skin grafting while the area is infected by these microbes is futile. Wound exudates of *proteus* infections have a characteristic unpleasant odor. These infections, although as a rule not serious on the skin, are very stubborn. Because of pronounced variations in susceptibility to antibiotics from strain to strain, sensitivity testing is essential for rational treatment.

Although not belonging to the family of *Enterobacteriaceae* but to the *Pseudomonadaceae*, the only member of clinical importance, namely, *Pseudomonas aeruginosa* (*B. pyocyaneus*), is discussed in connection with *proteus*,

because they quite often occur together in mixed infections and have other features in common. *P. aeruginosa* is a gram-negative, usually motile bacillus, which produces a highly diffusible greenish or greenish-blue pigment, and this organism has been long known to the surgeon as "blue pus" former. Like *proteus*, it is widely distributed in nature and occurs occasionally in the intestine. Similar to *proteus* it causes infections of the urinary tract, the middle ear, and particularly infections of burns and wounds. Meningitis, arthritis, and eye infections have been reported. The bluish-green color and a sweetish smell of the exudate is very characteristic. So far as chemotherapy is concerned the same rules apply as for *proteus* infections.

NEISSERIA GONORRHOEAE (GONOCOCCUS)

The gonococcus appears in exudates and cultures as a gram-negative diplococcus, with the adjacent sides flattened (coffee-bean shaped). The cultivation of the gonococcus presents certain difficulties, as it is fastidious and easily killed by drying or sunlight. Great care has to be taken in securing exudates, and best results with culture methods are obtained if the appropriate media are inoculated at the bedside. In acute disease of the male the finding of large numbers of morphologically typical intracellular or extracellular organisms on stained films may seem sufficient corroboration of the clinical diagnosis.

The surgeon is, as a rule, confronted with complications or sequelae of the primary gonococcal infection. Infection of the urogenital tract in the female is a frequent complication of gonorrheal cervicitis; urethritis, infection of Skene's or Bartholin's glands, salpingitis, and peritonitis are the lesions caused by lymphatic spread or direct progression. A creamy mucopurulent discharge is characteristic of gonorrheal infection. Fibrotic occlusion of the Fallopian tubes may necessitate surgical measures. In the male, prostatitis, urethral strictures, and epididymitis are the common complications of urethritis. Invasion of the blood stream by the gonococcus may take place and produce arthritis, fibrositis, iritis, endocarditis, pericarditis, and occasionally meningitis. In the

acute state, penicillin, 200,000-300,000 units, will cure the majority of cases. Localized complications, such as arthritis or Bartholin abscesses, may require surgical drainage and local instillation of penicillin as well as systemic treatment

PARVOBACTERIACEAE

The family consists of several genera and includes a large number of species, all of which are primarily of interest to the physician. A few species cause abscesses and other lesions which require surgical attention

Pasteurella.—*Pasteurella multocida* and *Pasteurella tularensis* appear to be the two species which need to be considered. Both are gram-negative, short, nonmotile, oval bacilli, the latter may show great pleomorphism. *P. multocida* grows readily but *P. tularensis* needs special media for primary isolation and will be missed unless there is some indication given to the laboratory of the suspected type of infection. *P. multocida* occurs as saprophytes and parasites in many animals and can be found frequently in the upper respiratory tract of normal domestic animals. Human infections in the form of abscesses, frequently complicated by osteomyelitis, are generally due to animal bites, particularly cat, dog, and rabbit. Generalized infections and cases of meningitis and empyema have been reported. All the strains of *P. multocida* which have been tested were sensitive to penicillin (Schupper, 1947).

P. tularensis is the causative agent of tularemia. The main sources of infection for man are (1) direct contact with infected animals, (2) the bites of ticks and flies (deer flies), (3) ingestion of contaminated meat or water, (4) laboratory infections. Some occupations show a higher incidence of infections. Hunters, farmers, and laboratory workers. If the organisms penetrate the skin, a primary lesion in the form of an ulcer develops in a certain percentage of cases. Spread occurs along the deep and superficial lymphatics, leading to lymphangitis and lymphadenitis with suppuration. This is the type of tularemia infection which the surgeon encounters. Generalized signs of fever and elevated sedimentation rate are always present, the white count may or may not be elevated. A transitory bacteremia

is usual during the first week but disappears as soon as antibodies are formed, but spread of the infection by the lymphatic route may take place with renewed, usually fatal, invasion of the blood stream, unless checked by treatment. The diagnosis can be made by the isolation of *P. tularensis* from the primary lesions or the pus from lymph nodes in the early stages. If isolation of the organism fails, the clinical diagnosis can be confirmed in the later stages of the disease by serologic methods.

Agglutinating and complement fixing antibodies appear in the blood from the second week on and show a rising titer during the third and up to the fifth week. These antibodies may persist for many years or even through life. A positive test, therefore, does not necessarily indicate present infection with *P. tularensis*, but the rise in titer between the second and third week of a disease suspected to be tularemia is of a great diagnostic significance. An intradermal test with specially prepared antigen (Foshay, 1940) is of diagnostic value. It shows the tuberculin type of reaction 48 hours after inoculation and is usually positive earlier than the agglutination test. The altered skin reactivity may persist for the remainder of life. Tularemia had been a highly fatal disease until streptomycin became available, this antibiotic has an almost immediate effect and a short course of six days has been found effective, even in the pneumonic form of tularemia, if treatment is started early in the course of the disease. The tetracyclines have been used in a number of cases with very satisfactory results.

Brucellaceae.—*Brucella abortus*, *Brucella melitensis*, *Brucella abortus*, and chronic brucellosis, a relatively common disease on the North American continent. Although primarily a systemic disease with which the physician has to deal, brucella infection may lead to localized lesions in bones and joints and as such becomes the concern of the surgeon. Because of the great difficulties in diagnosis, it appears important to draw the attention of the surgeon to this type of infection and make him conscious of the fact that brucellosis gives rise to a variety of lesions.

Brucella is a gram negative, small, non-motile rod, which causes disease in ungulates

transmissible to man. The difficulties of isolation, particularly in chronic cases, have been stressed by all workers, and *Brucella abortus* requires increased CO₂ tension for isolation. The main source of infection is unpasteurized milk, milk products, and infected meat. The localized lesions are mainly granulomatous in character, and proliferation of the cells of the reticuloendothelial system forms the basis of the lesions. The clinical picture has so many variations that the multiplicity of symptoms as such is often suspicious. The only exact diagnosis can be made by the isolation and identification of the organism which, as already mentioned, is beset with difficulties. Skin reaction to *Brucella* vaccine or brucellergin and the agglutination test and the opsonophagocytic index are diagnostic adjuvants, but only of relative value. As immunity reactions may persist for many years, a positive test is the only evidence that exposure to *Brucella* occurred at some time but does not necessarily indicate an active infection. Negative results, on the other hand, do not exclude active brucellosis (Huddleson, 1943). Bone and joint complications of brucellosis are probably not very frequent, but the small number of reported cases may be misleading because of the rarity with which the diagnosis can be established with certainty. Arthralgia in multiple joints seems to be a common symptom, but suppurative arthritis, osteomyelitis, and spondylitis have only more recently been given proper attention. Every attempt should be made to verify the clinical diagnosis by the isolation of the microbe in order to institute therapy. Streptomycin in combination with a tetracycline is the accepted form of treatment.

Bacteroidae.—*Bacteroides* are small, anaerobic, gram-negative, pleomorphic, non-spore-forming bacilli; their normal habitat is on the mucous membranes of the body. They cause putrid infections of wounds either alone or in combination with other bacteria. Post-partum infections, tonsillar abscesses, and subphrenic abscesses are the main lesions caused by this genus. Blood stream invasion from any of these foci may occur, with metastatic abscess formation and a high fatality rate in the reported cases. Anaerobiosis is essential for isolation, and it seems probable that such in-

fections are missed unless anaerobic cultures are routine in the laboratory. McVay and co-workers (1949) reported two cases successfully treated with chlortetracycline. In vitro test showed the organisms (*B. funduliformis*) resistant to penicillin, sulfonamides, and streptomycin.

BACILLACEAE

Only one species of the aerobic genus *Bacillus* is pathogenic, causing the infection known as anthrax. *Bacillus anthracis* is a facultative, aerobic, gram-positive, spore-forming, capsulated, nonmotile bacillus, occurring often in long chains. Growth occurs readily on conventional laboratory media. The spores are very resistant and may survive for years in earth or other materials. Anthrax is primarily a disease of domestic animals; human cases are relatively rare and occur mainly in men occupied in certain industries dealing with hides or skins, or in agricultural workers. Shaving brushes and furs may be rare sources of infection. Cutaneous anthrax (malignant pustule) starts as a small red spot which shows a central blister and some edema. In the blister fluid the anthrax bacillus can be readily found. During this stage the nature of the lesion may not be recognized unless the occupation of the patient rouses suspicion. In later stages the necrotic center of the lesion with the black crust "eschar" and the usually marked edema are characteristic of anthrax. Enlargement and tenderness of the regional lymph nodes are frequently present, and depending on the severity of the infection, systemic signs and symptoms of fever and prostration occur. The bacteriologic diagnosis is made by direct culture or inoculation of exudate into mice or guinea pigs and subsequent culture. In severe unchecked infections bacteremia occurs, and the mortality rate of such untreated patients may be as high as 20%. Surgical incision of the primary lesion is contraindicated, and early recognition of the true nature of this infection will prevent dangerous interference which may lead to bacteremia. Penicillin is the drug of choice, and treatment should be maintained at least until bacteria disappear from the lesion. Good results have been obtained with antiserum.

CLOSTRIDIUM

Clostridium is of much greater practical importance to the surgeon. This genus contains a large number of species of which only some are pathogenic for man, among them the organisms connected with gas gangrene and tetanus. The clostridia are gram-positive, anaerobic, rod-shaped organisms producing endospores; many species are motile. They occur naturally in soil and the intestinal tract of man and animals. Under anaerobic conditions most species grow on a variety of media and can be differentiated on the basis of biochemical reactions. The clostridial species most commonly present in gas gangrene elicit their effect in the tissues, and the systemic signs and symptoms are caused by toxins and enzymes produced by the bacterial cells. In most infections more than one pathogenic species is present and various nontoxin-producing saprophytic species occur in the same wounds. The following species are regarded as primary cause of gas gangrene (Reed, 1949), *Cl. perfringens* (Welch's bacillus), *Cl. novyi*, *Cl. septicum*, *Cl. bisfermentans* (*Cl. sordellii*), and rarer *Cl. histolyticum*. Other organisms (gram-positive cocci and gram-negative rods) are frequently present in the wounds with clostridia. As all clostridia require more or less strict anaerobic conditions, special features of the wounds are essential for their implantation and multiplication. Crushing injuries of the tissues, with foreign bodies, bone splinters, clothing, and soil particles, provide an ideal basis, and the virulence of the particular species introduced determines the severity of the infection. Local defense mechanisms of the host seem to be interfered with by the necrotizing and leukocidal toxins. The isolation of pathogenic clostridia from the wound does not necessarily imply clinical gas gangrene as there are wide variations in toxigenicity of different strains of the same species. The five mentioned species of *Clostridium* elaborate soluble exotoxins. *Cl. perfringens* has been divided into four types, A, B, C, and D, on the basis of seven different toxins, but only type A has so far been isolated from human infections. Type A produces so-called alpha toxin which has been identified as lecithinase and forms the main lethal component of culture filtrates. Other

enzymes produced by *Cl. perfringens* are hyaluronidase and kappa toxin, a collagen-splitting enzyme, and a variety of additional enzymes have been isolated and studied. All these enzymes appear to be of importance for the growth and multiplication of *Cl. perfringens* in the tissues and the majority of the histologic changes in the muscles can be produced with culture filtrates. Other pathogenic species of clostridia have also been studied as to their toxin and enzyme systems (DeSpain Smith, 1949). All elaborate soluble toxins which are neutralized by specific antitoxins. The toxins have lethal, necrotizing, and hemolytic actions either due to a single or to multiple substances.

The clinical picture of gas gangrene infection is characterized by edema of the subcutaneous tissues; the muscle fibers are friable and discolored, gas bubbles may appear between muscle fibers and the surrounding tissues and account for "crepitation." A blood-stained, often foul-smelling, thin exudate is discharged, containing gas bubbles. If highly proteolytic species take part in the infections, rapid and widespread tissue destruction takes place. Systemic signs and symptoms of severe toxemia with leukopenia, fever, and high pulse rate may be marked. Invasion of the blood stream by one or more species can occur. The clinical picture is not characteristic for any specific type of clostridial infection but the local picture in infections by a single species is often characteristic and very different from that of mixed infections.

In clinically established gas gangrene, time is of the utmost importance, and treatment with antitoxin must be started at once. Polyvalent antitoxin (*Cl. perfringens*, *Cl. septicum*, and *Cl. novyi*) standardized in international units should be given either intravenously or intramuscularly, depending on the gravity of the infection. The antitoxins are prepared by immunization of horses, and the necessary precautions have to be taken to prevent serious incidents due to hypersensitivity. The minimal recommended dose in established infections is three times the prophylactic dose (9,000 units *Cl. perfringens*, 4,500 units *Cl. septicum*, and 3,000 units *Cl. novyi*). This dose should be repeated every four to six hours according to the response of the patient. Chemotherapy

must be considered an adjuvant only to surgery and antitoxin. Local applications of bacitracin and penicillin as well as systemic treatment is advisable, because relatively little will penetrate into the ischemic parts from the circulation.

Clostridium tetani belongs to the same genus as the organisms causing gas gangrene, but provokes an entirely different clinical picture. *Cl. tetani* is a slender gram-positive bacillus with terminal spores and requires very strict anaerobic conditions for growth. It is widely distributed in soil and occurs occasionally in the feces of man and horses. Due to the almost universal use of toxoid for active immunization, tetanus has become a very rare disease, and many a surgeon may not encounter a case during his active life, but on the other hand the very fact of its rarity may cause diagnostic difficulties in the critical early stages of tetanus with possible fatal consequences for the patient.

Tetanus—Tetanus is a typical example of a pure toxemia; all clinical signs and symptoms are due to the action of the toxin and not to the multiplication of the bacteria. Tetanus may follow certain penetrating types of wounds, infections of burns and severe frostbites, or, fortunately, rarely surgical procedures, particularly in abdominal surgery and extractions of teeth. An interesting case has been reported by Murray and Denton (1948) in which clinical tetanus was almost certainly contracted from plaster of Paris. Certain conditions of the wound favor, and are almost a prerequisite for, the germination of *Cl. tetani*. Deep penetrating wounds with associated infection or foreign bodies provide the anaerobic environment which is necessary, but the wound may be very small and even apparently healed by the time clinical tetanus develops. It has been shown experimentally that if washed spores are introduced into healthy tissues, they are taken up by phagocytes and may be eliminated, but if the tissues are damaged and necrotic, the spores germinate and toxin is elaborated. It should be remembered that spores may persist in the tissues for a considerable time. If and when the toxin reaches the anterior horn cells of the nervous system, clinical symptoms of tetanus become manifest.

The pathway of the toxin is still a controversial subject, two main hypotheses exist: (1) toxin is absorbed by the motor nerve endings and reaches the anterior horn cells through the axis cylinders; (2) toxin is carried by the arterial blood to the central nervous system. The latter theory is receiving most support at present. The incubation period in tetanus varies considerably and may be as short as 3-4 days or as long as several weeks, with an average of 10 days. The prophylactic use of tetanus antitoxin after injuries will either prevent tetanus completely or prolong the incubation period, and the clinical disease will be milder.

Clinically, stiffness of the neck, trismus, and difficulties in swallowing are often the first symptoms. Tonic contractions of muscles and very painful clonic spasms elicited by very trivial external stimuli follow. Contractions of the facial muscles produce the characteristic "risus sardonius." In later stages all the muscles are affected and death is due to respiratory failure. The temperature may be slightly elevated, the pulse is rapid, and the patient remains conscious until the end.

The **clinical diagnosis** should not present any difficulties even in the initial stages if the surgeon is alert to the possibility. The bacteriologic proof is often very difficult or even impossible without adequate specimens. As previously mentioned, the initial lesion may be completely healed, but even if a wound is present, relatively large amounts of tissues and debris from the depth of the wound must be available for cultures to provide some chance for the isolation of *Cl. tetani*.

Treatment—Once clinical signs and symptoms of tetanus are pronounced, the chances of recovery are slim, but good results have been obtained with large doses of antitoxin by various routes, provided complete removal of the focus is achieved. Constant sedation (paraldehyde, chloral, etc.) and muscle relaxants (curare) are essential to prevent exhaustion. In a large series of cases the continuous intravenous administration of mephenesin in addition to established schemes of treatment resulted in a considerably reduced mortality rate (Veronesi, 1956). Supplementary oxygen therapy is important. Antitoxin should be administered intrathecally

(10-20,000 units), intravenously (20-50,000 units), and intramuscularly (50-80,000 units) in the first 24 hours. The intravenous and intramuscular doses must be repeated and carried on, depending on the progress of the patient. Even more heroic doses will not save every patient, and the chief effort of the physician must be the prevention of tetanus by the prophylactic use of antitoxin (1,500 units) as soon as possible after injuries occur. Penicillin should be used to prevent secondary infections (pneumonia), and as *Cl. tetani* is sensitive to penicillin it may check multiplication in the focus, but it has no effect on the toxin absorption.

CORYNEBACTERIACEAE

Corynebacterium diphtheriae is a gram-positive, nonmotile, nonspore-forming bacillus of ten club shaped and usually arranged in palisades. Growth can be obtained under aerobic conditions on the usual laboratory media, but tellurite-containing media are generally employed to suppress the growth of other organisms and to permit differentiation of the three recognized types of *C. diphtheriae* (gravis, mitis, and intermedius). It produces a powerful toxin which is responsible for the disease.

The only interest for the surgeon is that occasionally wounds may become infected with *C. diphtheriae*, and because of the rarity of such infections in temperate climates, they frequently remain undiagnosed until the appearance of late paralysis causes suspicion. Every wound with a grayish slough or membrane and no tendency of healing should be suspected and cultured to arrive at the correct diagnosis. Penicillin is used as an adjuvant with antitoxin.

ERYSIPELOTHRIX

Erysipelothrix rhusiopathiae causes erysipeloid, a usually harmless cutaneous infection. The causative organism is a gram-positive, nonmotile, nonspore-forming bacillus. Growth is obtained under reduced oxygen tension on simple media or better on enriched media. Butchers and persons handling poultry and fish are prone to this infection. A purple erythema, with some edema and a slightly ele-

vated margin, is characteristic of this lesion, which occurs chiefly on the hands. The infection remains localized as a rule, although peripheral extension with central clearing is common. *E. rhusiopathiae* is sensitive to penicillin, and the use of it probably shortens the course, although the infection is self-limiting and treatment is not a necessity.

MYCOBACTERIACEAE

Mycobacterium tuberculosis of either human or bovine type is responsible for the clinical disease of tuberculosis. With the discovery of this bacillus in 1882 by Robert Koch, a common cause was found for an extraordinarily wide variety of lesions and clinical symptoms. Surgeons and physicians are equally concerned in the diagnosis and treatment of tuberculosis. *M. tuberculosis* is a slender bacillus, nonmotile and nonencapsulated. Its most characteristic property is the resistance to decolorization by acids, "acid fastness." Special media are used for the isolation of the tubercle bacillus from exudates or tissues, and growth is characteristically slow. Recently media and methods have been developed (Dubos and Middlebrook, 1947; Reed and Morganti, 1956) which permit more rapid growth.

The pathogenesis of tuberculosis is a very intricate subject and cannot be discussed even superficially in this chapter. The reader should refer to general textbooks of pathology or to special monographs (Rich, 1944).

Tuberculous lesions are either productive or exudative in nature, but both types may be present at the same time in the same organ. Microscopically and histologically the productive type of lesion is represented by "tubercle" formation. The exudative type resembles in its very early stages the inflammatory reaction caused by pyogenic organisms, and exudation of fluid and polymorphonuclear cell infiltration are its chief characteristics. This latter type of cell is soon replaced by mononuclear forms. The surgeon is primarily concerned with tuberculosis of certain tissues. These include the lymph nodes, bones and joints, kidneys, epididymis, prostate and seminal vesicles, the pelvic organs in the female, the intestinal tract, the serous membranes (peritonitis, pleuritis, pericarditis), the central nervous system (men-

ingitis and tuberculoma), the larynx and trachea. The clinical features, the differential diagnosis, and the surgical procedures are dealt with in the special chapters.

The *diagnosis* rests ultimately on the demonstration of virulent tubercle bacilli in the exudates or tissues. The finding of acid-fast bacilli on smears is presumptive but not conclusive evidence of tuberculous infection. Saprophytic mycobacteria and acid-fast strains of the genus *Nocardia* may resemble tubercle bacilli so closely that they cannot be differentiated on stained films. Relatively large numbers of organisms have to be present in a specimen to be detected on a smear, and cultivation and animal inoculation must be resorted to if early lesions are to be diagnosed. The histologic examination will often be of great help, but if tissue is being removed, part should be used for animal inoculation which will prove conclusively the presence or absence of virulent tubercle bacilli. X-ray examinations and tuberculin tests have only a limited significance compared with the cultural methods and pathogenicity tests. However, even one or two negative cultures do not rule out tuberculosis.

Treatment.—With the discovery of streptomycin by Waksman and Schatz (1944) active treatment of tuberculosis has become a reality. No longer need the physician and surgeon trust only to the defense mechanism of the body to overcome the infection with the help of such supportive means as rest and nourishment.

Streptomycin, in combination with para-aminosalicylic acid or isoniazid, has proved to be the most satisfactory method of treatment. The addition of PAS or INH to streptomycin delays the development of strains resistant to the latter by 2-3 months and also permits the use of lower doses of streptomycin with a lower incidence of toxic side effects. Neomycin and viomycin are active against *M. tuberculosis* but due to their toxicity must be used with great caution. Cycloserine is still undergoing clinical trials, as is streptovaricin. It is important to check the sensitivity of the patient's strain to these tuberculostatic drugs at regular intervals so that therapy may be altered upon the appearance of the slightest increase in resistance. Treatment based on

inaccurate sensitivity tests produces unreliable results (Pierce, et al, 1957).

The use of tuberculostatic drugs alone is not sufficient for tuberculosis but should be considered a very valuable adjunct to other established forms of treatment. In military tuberculosis and tuberculous meningitis it is the only promising treatment available. It is of great value to the surgeon as preparatory treatment before chest surgery and in the treatment of tuberculous sinuses and tuberculosis of the bones and joints. Indeed, most forms of tuberculosis are benefited by these drugs improving the general condition of the patient, thus making surgery possible.

ACTINOMYCES

Actinomyces bovis and/or *israeli* is the cause of actinomycosis in man. *A. bovis* is a gram-positive, branching, filamentous, nonmotile organism. No spores are formed. Pus from actinomycotic lesions frequently contains "sulfur granules," whitish or yellowish firm granules which, when slightly crushed and viewed under the microscope, show entangled filaments with swollen clublike ends. This appearance, which is also characteristic in histologic sections, is responsible for the name "ray fungus." *A. bovis* can be grown on usual laboratory media under anaerobic conditions. Growth is slow, taking generally 4-6 days at 37° C. *A. bovis* seems to be a strict parasite and has not been found outside the human or animal body. It can be found in scrapings from the teeth, gums, and tonsillar crypts in apparently healthy persons, and the disease is due to an endogenous infection. Although the exact pathogenesis is little understood, trauma, e.g., tooth extractions, fractures of the jaw, or other injuries to the mucous membranes of the mouth, appears to favor the invasion of *A. bovis*. The relative rarity of the disease suggests that as yet unknown factors must play an important role.

Actinomycosis is a subacute or chronic, slowly progressive disease, with three main localizations: the cervicofacial, thoracic, and abdominal regions. The first form is the most common and affects the soft tissues of face and neck. The lesions show marked induration and a peculiar hard consistency is felt.

The skin over the lesions is swollen and brownish red in color. If central softening and break through the skin occur, chronic fistulas are formed. The abdominal type starts usually in the appendiceal region and is commonly mistaken for a simple appendicitis. After appendectomy the poor healing of the wound and fistula formation and later the formation of a tumorlike mass should arouse suspicion. Thoracic actinomycosis affects the lungs, and, if undiagnosed and untreated, will form abscesses and cavities. All three spread slowly but relentlessly, even eroding bone

because, as pointed out, the mouth is the normal habitat of *A. bovis*.

Penicillin is considered the treatment of choice. Rather high doses should be given, one to five million units per day for a minimum of from 6-8 weeks. Surgical excision or drainage may be indicated in some cases.

NOCARDIA

Some species of the genus *Nocardia* are pathogenic for men, causing chronic suppurative or granulomatous lesions. *Nocard*

Fig. 9—Actinomycosis of the neck of 2 months' duration following tooth extraction

Hematogenous spread with metastases in many organs has been observed. The clinical diagnosis of actinomycosis can be verified only by the cultivation and isolation of *A. bovis*. The microscopic demonstration of gram-positive filaments or of typical "ray fungus" in histologic sections is acceptable as provisional diagnosis, but cultural isolation should be at least attempted. This presents usually no difficulty in material from primarily closed lesions, provided the laboratory receives some indication of the presumptive diagnosis from the surgeon and cultures are kept long enough. The isolation from heavily contaminated material is more difficult, but if proper methods are used it is generally successful. The interpretation of positive findings from sputum requires caution

are gram-positive rods and branching filaments, some species are partially acid fast and these may be mistaken for tubercle bacilli in stained films. In pus or exudates from lesions, granules similar to the "sulfur granules" in actinomycosis can be found. *Nocardia* can be grown on simple media under aerobic conditions but growth is slow.

Nocardiae occur freely in nature, and infection is either air-borne through inhalation or by introduction into the subcutaneous tissue through trauma. Pulmonary *nocardiosis* resembles tuberculosis both by x-ray and in clinical symptomatology. Hematogenous spread leads to metastatic lesions throughout the body from lesions and meningitis may be caused by *Nocardia* either as primary lesions

or as metastatic lesions from the lungs. In the majority of reported cases the diagnosis was made only after death. The lesions of the subcutaneous tissues and bones are easily mistaken for actinomycosis or fungus infections. Multiple draining sinuses are characteristic of these lesions, which result in the clinical picture of Madura foot. Generalized granulomatous disease due to a *Nocardia* species has been reported recently by Cuttino and McCabe (1949). The frequency of *Nocardia* infections is difficult to estimate, but it is probably higher than the reported cases would indicate. The pulmonary type has had a very high mortality rate. The correct diagnosis can be made only by the isolation and identification of the organism. Sulfadiazine is the drug of choice, but the addition of streptomycin or one of the tetracyclines may be advisable. Treatment should be continued even after clinical manifestations have subsided (Peabody and Seabury, 1957).

SYSTEMIC MYCOTIC INFECTIONS

Most of the fungi responsible for systemic mycotic infections in man belong to the *Fungi imperfecti*. As the isolation media and methods for these organisms differ from those customarily used for bacteria, the fungus etiology of a lesion or disease must be suspected in order to make the proper provisions and arrive at the correct diagnosis. Contrary to earlier beliefs, fungus infections are now known to be widely distributed and even to occur occasionally in epidemic form. Some are world-wide in distribution, and others are restricted to certain areas. Most of the systemic infections are not transmitted from man to man but are acquired from exogenous sources, infected soil, and dust. The clinical manifestations are protean in nature and may resemble those of other chronic diseases such as tuberculosis, syphilis, and tumors. Early and accurate diagnosis is essential, and surgical excision and drainage may be indicated and of definite value. The treatment up to very recently has been mainly supportive, but newly discovered chemotherapeutic agents appear very promising.

Sporotrichosis—This infection is caused by *Sporotrichum schenkeri*. This fungus can be

grown on the common laboratory media and forms characteristic colonies on Sabouraud's agar. The isolation of the fungus is the only exact method of diagnosis. The fungus causes subacute or chronic granulomatous lesions usually on the exposed parts of the body. The primary lesion appears in the form of a rather uncharacteristic-looking abscess or ulcer which fails to heal. From this initial lesion the fungus invades the lymphatics, and a very typical clinical picture develops: chronic lymphangitis with multiple subcutaneous abscesses along the lymph vessels. The abscesses rupture and chronic ulcers without tendency to healing appear. These ulcers are usually secondarily infected with staphylococci or other organisms, and if only the superficial exudate is taken for cultures, the lesions are frequently diagnosed wrongly. Pus or exudate from unbroken lesions should be cultured. A skin test with heat-killed suspension of the fungus shows a positive reaction of the tuberculin type after the first week of disease.

The infection responds to treatment with iodides (Lugol's) orally, but such treatment has to be continued over a period of months.

Blastomycosis.—This is a granulomatous disease of the skin or internal organs caused by *Blastomyces dermatitidis*. This fungus grows on the usual laboratory media and shows two types of growth, a yeastlike colony when grown at 37° C and a moldlike form at room temperature. *B. dermatitidis* frequently infects the lungs and can be mistaken for tuberculosis. Spread via the blood vessels occurs and metastatic abscesses appear in the skin, the bones, liver, spleen, and central nervous system. Primary infection of the skin consists of ulcers with a raised, irregular, papilliform border showing milium abscesses. The differential diagnostic considerations in both the cutaneous and pulmonary (systemic) forms comprise a number of other fungus infections, infectious and noninfectious granulomas, and tumors. The isolation and identification of the fungus from the exudate provide the only accurate means of diagnosis. For the cutaneous forms a combination of iodides, x-ray therapy, surgical procedures, and desensitization with vaccines has given the best results. The treatment of the systemic form has become more promising since the introduction

of the aromatic diamidines, stilbamidine, and 2-hydroxystilbamidine. In localized pulmonary blastomycosis, lung resection may be a valuable adjunct to treatment with stilbamidines (Curtis and Bocobo, 1957). The newly discovered fungistatic, amphotericin B, may revolutionize the treatment of this infection

Fig 10—Multiple cutaneous lesions caused by *Blastomyces dermatitidis* showing raised irregular papilliform borders with milium abscesses

Coccidioidomycosis (Coccidioides immitis).—This is caused by *Coccidioides immitis*. The occurrence of this organism appears to be confined to certain endemic areas (San Joaquin Valley in California, parts of Texas, and Arizona, etc.), where it has been found in the soil and is transmitted by dust. In the majority of cases infection of the lung through place, primary infection of the skin through wounds is rare. The upper respiratory infection of the acute type manifests itself with the signs and symptoms of a bronchopneumonia with fever and chills and is known as San Joaquin fever, or Valley fever, which is generally a nonfatal, self limited infection. Dissemination may occur and gives rise to the generalized form, known as coccidioid granuloma, which resembles tuberculosis very closely,

both on clinical and x-ray findings. Lesions may appear anywhere in the body, and the mortality rate is very high (50-60%). The diagnosis can be made by the cultivation of *C. immitis* from exudates or by the inoculation of mice and guinea pigs with pleural fluid, sputum, etc. However, the risk of infection to nonimmune laboratory personnel is so great that cultural isolation should be attempted only under special circumstances. A positive skin reaction of the tuberculin type to coccidioidin can be elicited by the third week following infection. In patients with disseminated disease the skin test may be negative. Complement fixation and precipitation tests have been developed and are used as diagnostic aids. In disseminated coccidioidomycosis all available forms of treatment must be tried: stilbamidines, amphotericin, and surgery. Winn (1957) discusses the present concept of the surgical management

Histoplasmosis.—This is essentially a disease of the reticuloendothelial system caused by *Histoplasma capsulatum*. On cultures this organism grows in two morphologic forms depending on the medium used and the temperature of incubation. On blood agar at 37° C and in tissues, *H. capsulatum* appears as small oval budding yeast cells which in tissue sections are found inside the cells. The natural reservoir of *H. capsulatum* is the soil, and all available evidence indicates that histoplasmosis is an air-borne infection. The majority of infections is not clinically apparent. This fact has been recognized only since the histoplasmin skin test has been extensively employed as an epidemiologic tool. The clinical manifestations of the active infection with the fungus are manifold, and in the differential diagnosis many other acute and chronic infections, tumors, and granulomas must be considered. Of special interest to the surgeon are the "coin" lesions and multiple calcifications due to healed histoplasmic infections. The diagnosis depends on the isolation of *H. capsulatum* from the peripheral blood, the bone marrow, lymph nodes, or skin ulcers, or on the demonstration of the organism in histologic sections. Skin sensitivity to histoplasmin develops during the third or fourth week after

infection A positive reaction has the same significance as a positive tuberculin test Complement fixing and precipitating antibodies can be demonstrated in the serum at about the same time Spontaneous recovery appears to be the rule and fortunately only the rare disseminated case ends fatally The experiences with amphotericin are too recent and few to permit any predictions of its effectiveness in the disseminated form, although promising results have been reported (Lehan, et al, 1957)

Cryptococcosis (Torulosis).—This fungus infection due to *Cryptococcus neoformans* shows a decided preference for the central nervous system *C. neoformans* is a budding yeastlike organism, showing both in cultures and tissues or exudates a large capsule *C. neoformans* can be easily cultured on ordinary laboratory media The central nervous system is the most frequently affected organ either primarily or secondarily from lung or skin lesions Clinically the infections resemble tuberculous meningitis, brain abscess, brain tumor, or syphilis The cutaneous lesions appear in the form of subcutaneous abscesses or tumors which break through the skin and form ulcers Generalized spread from the skin lesions almost invariably involves the central nervous system as well as the lungs, liver, spleen, etc The diagnosis is made by the demonstration of the fungus in exudates, by cultural isolation, or animal inoculation (mice). A drop of spinal fluid or pus or other exudates, suspected of containing *C. neoformans*, should be mixed with a drop of India ink on a slide under a cover slip When viewed under the microscope the fungus appears as a round, budding cell surrounded by a large capsule No generally effective treatment of cryptococcosis is known The central nervous form is almost invariably fatal Improvement in some cases has been reported after the use of iodides, sulfa drugs, and x-ray, but it is by no means consistent The new antifungal agent, amphotericin B, appears to offer some promise.

Other fungi may occasionally cause lesions which have to be differentiated from other infections For detailed information on fungus infections of medical importance, the student should consult special textbooks (Conant, et al, 1954)

MIXED INFECTIONS

This discussion has been concerned with the more common bacterial and fungal agents that cause infections of interest to the surgeon. Although the frequent involvement of more than one microbe in these infections has been mentioned in various connections, the great practical importance of mixed infections deserves emphasis A few examples might illustrate this point

Sputum or bronchial aspirations from bronchiectasis or lung abscesses yield as a rule a highly mixed flora, containing many aerobic as well as anaerobic species Even under optimal conditions not all species will be isolated, and those isolated cannot always be completely identified within a reasonable time. Spirochetes and fusiforms commonly present in such specimens can only be demonstrated on smears It is often difficult or impossible to determine the initial cause of the infection or to assess the exact role of the various species present The choice of a suitable chemotherapeutic agent can be based only on the predominating flora

The situation is similar in cases of peritonitis following rupture of the gut. Here, too, the great variety of organisms cultured makes exact identification and sensitivity testing of each species impractical If the infection remains localized, topical treatment with a mixture of bacitracin-neomycin will often be effective However, in severe infections systemic antibiotic treatment is indicated

Infected burns also present special features Large areas of the body are exposed to bacteria, and in addition to accepted pathogens, a number of "opportunists" may complicate the picture One of the principal surgical objectives is to avoid infection in burns of a limited area (e.g., of the hand by early excision of the burned area, about the third or fourth day, with immediate skin grafting) and to minimize and control the infective process in the more extensive burns A word of caution is in order here on the use of corticosteroid hormones in these cases The general state of the patient may make their use imperative, but in such cases the surgeon must be on guard against possible spread of the infection and must administer systemic as well as local treatment with a suitable, effe

CONCLUDING REMARKS

In the diagnosis of infections the proper taking of specimens is of the utmost importance. Even the best bacteriologic laboratory can only isolate the flora in the specimen received. Certain principles have to be kept in mind to make a quick and accurate diagnosis possible, and the physician and surgeon have to contribute their parts.

1. The introduction of contaminating organisms must be prevented, instruments used for taking the specimens and the containers must be sterile.

2. Specimens should be taken from the freshest lesions, and the site of progressive infection, e.g., from the edges of ulcers, from unopened abscesses, rather than broken ones, whenever possible.

3. Sufficient material should be collected, so far as feasible, if various examinations are required or when the chances of finding the causative organism increase (up to a point) with the amount of material available (e.g., 24-hour specimens of urine for the demonstration of tubercle bacilli).

4. Information on the clinical condition of the patient and on any treatment received has to be given to the laboratory to aid in the selection of suitable media and techniques; whenever possible specimens should be collected before treatment is started. In problem cases the collaboration of the surgeon and laboratory chief is essential for results and their evaluation.

5. Last but not least, specimens should reach the laboratory as soon as possible after they have been obtained, to prevent drying or other injuries to fastidious organisms.

Physiopathology

As to fluid loss there is a decrease in output resulting from inadequate contraction of the ventricles because of a decrease in venous return. There is no significant change in hemoglobin or hematocrit levels in hemorrhage, except hours later. However, the reduction in blood volume and plasma loss or dehydration, there is a decrease in oxygenation early.

Metabolic changes in shock are characterized by hypoxia resulting from deficient

There is an acidosis with a fall in pH. Impaired renal function is manifested by a rise in plasma NPN and a demineralization of urine. Acute renal failure, especially lower nephron nephrosis, may be discussed later. Impairment of function may occur with serious consequences in terms of its role in protection against infection as mentioned elsewhere. Mentally it has been shown that the liver also contributes to the state by the elaboration of humoral factors. In profound shock the kidney produces a constrictor principle called VEM* and also a vasodilator material called VDM. As the animal approaches the stage of irreversible shock, VDM appears in the blood in large amounts. In animals made resistant by previous graded exposures, there is a decrease in the blood VDM.

The brain is very susceptible to anoxia. If the anoxia is prolonged or severe, there may be a period of apparent recovery, coma, convulsions, and death.

There are also compensatory changes consisting of vasoconstriction and hemodilution.

EM = vasoconstrictor material.

The effect of the former is to reduce the size of the vascular bed by selective vasoconstriction in the skin and kidneys. It has been estimated that approximately 500 ml of blood normally contained in the vessels of the skin are thereby made available for vital organs such as the brain. Vasoconstriction in the vessels of the kidneys may have a damaging effect as mentioned above. Vasoconstriction is also important in that, by maintaining blood pressure at or near normal levels, it may mask severe hemorrhage and impending shock. In severe or untreated cases of shock, the mechanism ultimately fails.

A less effective compensatory mechanism is hemodilution. By this means the reduced blood volume is partially restored by passage of water and electrolytes from tissue spaces into the blood stream. Hemodilution may not occur in dehydration or in severe anemia. Vasoconstriction and hemodilution cannot be relied upon, therefore, to maintain an adequate blood volume in cases in which hemorrhage has been severe or prolonged.

Pathologic Anatomy

Except for the characteristic findings of the complications and consequences of shock, i.e., acute renal failure, myocardial infarction, etc., to be discussed later, there are no abnormal changes. The organs may be pale or plethoric, depending on the amount of blood administered.

Diagnosis

The clinical features of shock—the signs and symptoms such as restlessness, subnormal temperature, rapid pulse, pallor, sweating, cold extremities, and low blood pressure, and the metabolic and other changes already described—are those of the fully developed state. It is the early recognition of the causes of reduction in blood volume that should be the aim of diagnosis in order to prevent shock and its grave effects.

The most common cause of reduction in blood volume is hemorrhage. The hemorrhage may be either external or internal. It may be traumatic; it may occur during or following surgery; or it may be spontaneous, e.g., peptic ulcer, ruptured ectopic pregnancy, or purpura.

Shock and Blood Transfusion

Paul G. Weil, MD.

SHOCK

No subject in surgery is of greater importance than shock. Despite a better understanding of its causes and treatment gained from the many investigations of the problem and by the development of blood banks and transfusion services during recent years, shock still remains a dreaded complication of surgical operations and trauma.

Shock, also known as *collapse* or *peripheral circulatory failure*, may be defined as the syndrome characterized by subnormal temperature, pallor, cyanosis, sweating, cold extremities, thirst, low urine output, and low blood pressure due to a reduction in blood volume usually the result of hemorrhage.

Until a few years ago, shock perhaps even excelled eclampsia as the "disease of theories." There was general agreement that the main factor in shock was an acute reduction in blood volume, but there was, however, a difference of opinion on the cause of the decrease in blood volume.

Theories

The principal theories and those on which present day management of shock depends are as follows:

1 *Neurogenic* Nervous impulses originating from tissue damaged by trauma or at operation cause a dilatation of the vascular system, leading to a reduction in effective blood volume.

2 *Toxic* Noxious substances liberated by damaged tissue increase the permeability of capillaries, leading to loss of plasma from the circulation, reduction in blood volume, and hemoconcentration, i.e., a relative increase in the cellular elements of the blood.

3 *Hemorrhagic* The reduction in blood volume is due to hemorrhage resulting from trauma or operation or occurring spontaneously.

These conflicting theories have recently been resolved, and the following concepts are those now generally held. *Primary*, or *neurogenic*, shock is due to a dilatation of the vascular system. *Secondary*, or *oligemic*, shock, also known as *traumatic* and *surgical* shock, is due to a reduction in blood volume resulting from fluid loss.

The shock syndrome may also result from failure of the heart itself, so called *cardio-circulatory shock*. Various classifications of shock have been used. The one that follows is based on the mechanisms of its development.

- 1 Reduced blood volume
 - A Loss of blood
 - Internal e.g., ruptured spleen
 - External e.g., traumatic amputation
 - B Loss of plasma
 - Internal e.g., peritonitis
 - External e.g., burns, crushing injuries
 - C Loss of water and electrolytes (dehydration)
e.g., gastroenteritis

II. Dilatation of vascular system

- A. Physical and psychologic stimuli, e.g., pain, anxiety
- B. Drugs, e.g., anesthetic agents
- C. Surgical procedures, e.g., thoracic operations
- D. Acute abdomen, e.g., perforated peptic ulcer
- E. Infections

III. Cardiocirculatory

- A. Endocardial lesions, e.g., mitral and aortic stenosis
- B. Pericardial lesions, e.g., tamponade
- C. Myocardial lesions, e.g., infarct
- D. Arrhythmias, e.g., paroxysmal tachycardia

Physiopathology

In shock due to fluid loss there is a decreased cardiac output resulting from inadequate filling of the ventricles because of a diminished venous return. There is no significant change in hemoglobin or hematocrit levels in shock from hemorrhage, except hours later. When, however, the reduction in blood volume is due to plasma loss or dehydration, there is hemoconcentration early.

The metabolic changes in shock are consequent to the anoxia resulting from deficient circulation. There is an acidosis with a fall in CO_2 . An impaired renal function is manifested by a rise in plasma NPN and a decreased formation of urine. Acute renal failure, the so-called lower nephron nephrosis, may supervene as discussed later. Impairment of liver function may occur with serious consequences in terms of its role in protection against sepsis as mentioned elsewhere.

Experimentally it has been shown that the kidney and liver also contribute to the state of shock by the elaboration of humoral factors. In profound shock the kidney produces a vasoconstrictor principle called VEM* and the liver, a vasodilator material called VDM. As the animal approaches the stage of irreversible shock, VDM appears in the blood in increasing amounts. In animals made resistant to damage by previous graded exposures, there is a decrease in the blood VDM.

The brain is very susceptible to anoxia. If shock is prolonged or severe, there may occur after a period of apparent recovery, *coma*, *convulsions*, and *death*.

There are also compensatory changes consisting of *vasoconstriction* and *hemodilution*.

*VEM = vasoconstrictor material

The effect of the former is to reduce the size of the vascular bed by selective vasoconstriction in the skin and kidneys. It has been estimated that approximately 500 ml. of blood normally contained in the vessels of the skin are thereby made available for vital organs such as the brain. Vasoconstriction in the vessels of the kidneys may have a damaging effect as mentioned above. Vasoconstriction is also important in that, by maintaining blood pressure at or near normal levels, it may mask severe hemorrhage and impending shock. In severe or untreated cases of shock, the mechanism ultimately fails.

A less effective compensatory mechanism is hemodilution. By this means the reduced blood volume is partially restored by passage of water and electrolytes from tissue spaces into the blood stream. Hemodilution may not occur in dehydration or in severe anemia. Vasoconstriction and hemodilution cannot be relied upon, therefore, to maintain an adequate blood volume in cases in which hemorrhage has been severe or prolonged.

Pathologic Anatomy

Except for the characteristic findings of the complications and consequences of shock, i.e., acute renal failure, myocardial infarction, etc., to be discussed later, there are no abnormal changes. The organs may be pale or plethoric, depending on the amount of blood administered.

Diagnosis

The clinical features of shock—the signs and symptoms such as restlessness, subnormal temperature, rapid pulse, pallor, sweating, cold extremities, and low blood pressure, and the metabolic and other changes already described—are those of the fully developed state. It is the *early recognition* of the causes of reduction in blood volume that should be the aim of diagnosis in order to prevent shock and its grave effects.

The most common cause of reduction in blood volume is *hemorrhage*. The hemorrhage may be either external or internal. It may be due to trauma; it may occur during or following operation; or it may be spontaneous, e.g., from a peptic ulcer, ruptured ectopic pregnancy, thromboembolic disorders.

The large amounts of blood that may be lost in traumatic injuries or at operation have been shown in numerous studies. It can be anticipated that wounds which are caused by violent force and which result in extensive injury will be accompanied by shock.

Loss of blood into the soft tissues, body cavities, or gastrointestinal tract is difficult to evaluate. The swelling of soft tissues or the presence of dullness on percussion over body cavities is useful as an indication of the extent of hemorrhage.

Once shock has developed, the only reliable clinical guide is the level of the blood pressure (In individuals with hypertensive disease, the blood pressure may not fall below the normal range.) The pulse rate is not always increased. Blood studies such as hemoglobin or hematocrit determinations are of no use inasmuch as they do not reflect the changes in blood volume in hemorrhage. Blood volume estimations may be valuable in complicated cases, especially if a preoperative determination has been made.

Reduction of blood volume from *loss of plasma* most commonly occurs in cases of burns. Plasma is lost from damaged capillaries in and adjacent to the burned areas. The loss of plasma leads to hemoconcentration. In intestinal obstruction, especially when accompanied by local circulatory stasis as in mesenteric thrombosis, there may be a diffusion of plasma into the peritoneal cavity and bowel lumen with a resultant reduction in blood volume. The crush syndrome follows compression injuries to the extremities. When the compression is released, plasma is lost into the damaged tissues, and shock develops.

In conditions leading to *dehydration*, such as excessive vomiting, diarrhea, gastrointestinal fistulas, there is a reduction in blood volume due to loss of water and electrolytes from the blood.

Although of no use in hemorrhagic shock, the determination of the degree of hemoconcentration by hemoglobin or hematocrit studies is of great value in estimating the degree of reduction of blood volume from loss of plasma (or in dehydration) and in determining the amount of plasma (or saline) to be infused.

Shock resulting from a disturbance of the nervous regulation of vascular tone is next in importance to that due to hemorrhage. Various stimuli, psychic and physical, drugs, especially anesthetic agents, surgical procedures, and infections may cause peripheral vascular dilatation.

Cardiocirculatory or cardiogenic collapse is due to failure of the heart itself. Cardiac tamponade resulting from acute pericardial effusion or hemorrhage causes a characteristic syndrome of shock, venous engorgement, and dyspnea. Myocardial infarction is often accompanied by shock. The arrhythmias, paroxysmal tachycardia, and heart block may cause peripheral circulatory failure.

In cases of severe mitral or aortic stenosis sudden strain or the stress of major surgery may cause collapse due to the inability of the damaged heart to put out more blood on demand. The diagnosis of shock due to these causes depends on the history and physical and electrocardiographic findings.

Prophylaxis

Patients in shock withstand operative procedures poorly. As a rule, surgical measures should not be undertaken until shock has been relieved. When immediate operation is imperative to control hemorrhage or for other urgent reasons, transfusion should be started at once and continued throughout the operation.

In many patients with chronic disease there is often an associated anemia due to various causes, including malignancy, infection, and malnutrition. In such patients there is usually a reduction in total blood volume because the reduction in the red cell mass may be only partially compensated for by an increased plasma volume. The decrease in both the volume and particularly the oxygen-carrying capacity of the blood must be restored by transfusions of whole blood before major operations are performed on such patients. The usual practice is to give 500 to 1,000 ml. of blood, the amount depending on the degree of anemia, on each of several successive days immediately prior to the day of operation. Red cell suspensions as described later may also be used.

The detection of hemorrhagic tendencies, especially in diseases of the liver and gall bladder, by coagulation tests, e.g., prothrombin determination, and their correction will be discussed later.

The choice of an anesthetic demands great care when shock is either present or anticipated. Oxygen should be given continuously during anesthesia in all cases of shock to avoid anoxia. It is the responsibility of the anesthesiologist to watch for the early signs of shock in all operations, looking particularly for falling blood pressure. Blood pressure readings should be made repeatedly during the opera-

Shock may manifest itself not only during or at the end of operation but also at any time after the operation—even hours later. When shock occurs several hours after the end of an operation, it may be due to hemorrhage from a loose ligature. In such cases, transfusions will have only a temporary effect in restoring the blood pressure. Serious consideration must be given, therefore, to immediate reoperation for control of hemorrhage in all patients who develop shock following operation and in whom the blood pressure cannot be restored or maintained by transfusions.

Fig 11—Illustrates (1) the large amount of blood that may be lost at operation, in this case a pneumonectomy for pulmonary tuberculosis; (2) the development of shock during operation because of failure to maintain blood replacement *pari passu* with blood loss which was measured by the Wangenstein method, and (3) the proper treatment of shock by immediate, rapid, and adequate replacement of blood.

tion and at frequent intervals during the immediate postoperative period.

Careful surgical technique both in the gentle handling of tissue and in the use of hemostasis is important in minimizing hemorrhage.

Treatment

The treatment of shock consists principally in the replacement of the fluid lost and, to be discussed later, the use of vasoconstrictor drugs and hormones in cases in which vaso-

Fig. 13.—Illustrates (1) the large amount of blood that may be lost during surgical operation, in this case removal of mediastinal tumor, (2) the development of shock several hours after the end of the operation, and (3) the proper treatment of shock by immediate rapid and adequate blood transfusion

dilatation is a factor. In *hemorrhagic shock* there is no substitute for *whole blood*. Plasma transfusion, although it restores blood volume in this condition, does not improve the reduced oxygen-carrying capacity of the blood. The use of plasma or plasma substitutes in shock from hemorrhage should be confined to the emergency measure of restoring or maintaining blood volume during the period of delay necessary to the starting of a whole blood transfusion or in supplementing blood transfusion if supplies of blood are limited

Whole Blood Transfusion.—There are several devices frequently used for the rapid restoration and, with continuing blood loss, the maintenance of normal blood volume. Blood may be transfused into *several veins simultaneously*. It may be *forced in* by attaching the pump of a blood pressure apparatus to the air inlet tube of the transfusion bottle and applying pressure, care being taken to prevent the entrance of air into the flow of blood. In the severely shocked patient, with cold extremities, the peripheral veins are usu-

Fig 14—Technique of venipuncture.

Just as important as knowing *what to give* is knowing *how to give it*. In shock from hemorrhage, blood must be given *immediately*, and it must be given *rapidly* and often in *large quantities*, of the order of 5 to 10 liters. These three aspects of the treatment of shock cannot be overemphasized. They are determined not by one's impression of the amount of blood lost (which is usually an underestimation), or by the large amount which may have already been administered, but only by the response of the patient to transfusion as indicated by the level of the arterial blood pressure

ally contracted. Dilatation of the veins may be induced by the *application of heat* to the extremity to be used for transfusion. Since, however, time is of the essence in the treatment of shock, at the first indication that the collapsed state of the veins may delay a successful venipuncture, a "cut-down" should be started at once.

The technique of the "cut-down" is as follows. The site usually chosen is the ankle, although any of the larger veins in the arm may be used. If the ankle is chosen, the vein may be found lying immediately above and in front of the medial malleolus. Under local

SHOCK AND BLOOD TRANSFUSION

Fig 15—Routes for transfusion

anesthesia the vein is exposed with blunt dissection. It is separated from the surrounding tissues by placing the handle of a scalpel or other flat instrument between the undersurface of the vein and the skin. Two ligatures are then drawn between the vein and the skin; one is placed distally and tied around the vein; the proximal ligature is left untied. A small incision is made in the anterior wall of the vein between the two ligatures with a pair of scissors or other sharp-pointed instrument. A Lindemann needle or cannula is then inserted proximally for some distance into the vein and tied securely in place by means of the second ligature. The needle or cannula may be immediately connected to a transfusion set or kept patent by the attachment of a slow-drip intravenous solution of saline.

Intra-arterial transfusion has recently been introduced as a method to be used in profuse hemorrhage or profound shock when restoration of the blood volume by the intravenous route is ineffective. The transfusion is usually administered via one of the arteries of the hand,* most often the radial. By means of pressure, blood may be forced retrograde into the arterial system so as to fill rapidly the renal, coronary, and cerebral vessels simultaneously with the restoration of blood volume. Recent studies indicate, however, that the important factor is the rate rather than the route of transfusion.

Plasma Transfusion.—The treatment of shock due to a reduction in blood volume from loss of plasma as in burns, intestinal obstruction, or peritonitis is the infusion of plasma, albumin, whole blood, or plasma expanders. Dehydration due to vomiting in such cases must be treated with saline infusion. When present, infection, which may cause vasodilatation, must be treated with antibiotic and vasopressor drugs.

The circulatory collapse that may supervene with *dehydration*, in patients with the low-salt syndrome, in diabetic coma, the crisis of adrenocortical insufficiency, or acute gastroenteritis, should be treated with saline infusions, blood transfusion, and the specific hormone and antibiotic indicated. Vasopressor drugs may also be useful.

*In a right-handed patient, intra-arterial transfusion should be given in the left hand.

Vasoconstrictors.—The decline in blood pressure that may result from spinal anesthesia is prevented by using ephedrine before anesthesia, and it is treated by using Neo-Synephrine or other vasoconstrictor agents. Norepinephrine is used rather than epinephrine because of the danger of the latter drug causing cardiac arrhythmia in the presence of anesthesia and because of its constriction of the coronary vessels. Vasoconstrictor drugs are also used more and more frequently to maintain normal blood pressure postoperatively and to restore blood pressure in cases of shock due to blood loss.

Collapse may be severe in fulminating infections, in contaminated wounds of the abdominal cavity or perineal region, and following transfusion of contaminated blood. The intravenous and intramuscular injection of wide-spectrum antibiotics early and in large dosage is imperative. Replacement of blood, plasma, and electrolytes and the use of vasoconstrictors, as in the treatment of shock due to other causes, are also required.

Transfusions are usually contraindicated in the treatment of cardiogenic shock. Cardiac tamponade is treated by pericardial paracentesis or thoracotomy. The shock accompanying myocardial infarction is treated with norepinephrine. Therapy of the arrhythmias that may result in shock is described fully in other texts.

Adjuvant Measures.—Although transfusion is the main measure in the therapy of secondary shock, there are other adjuvant measures which have a valuable place in its treatment.

1. The control of hemorrhage is obviously of utmost importance.

2. Vasoconstrictor drugs are valuable agents in counteracting vasodilatation and in restoring the reduction in effective blood volume in cases of neurogenic shock. Their use in cases of secondary shock is less satisfactory. Since, however, there may be an element of neurogenic shock in cases of hemorrhage, it is often desirable to use them in certain circumstances, i.e., trauma, or infection accompanying hemorrhage. The use of adrenergic blocking agents such as chlorpromazine, which are beneficial in the prevention of shock in the experimental animal, has its rationale in their vasodilating effect on the vessels of kidney and other vital

SHOCK AND BLOOD TRANSFUSION

organs whose blood supply in prolonged shock may be greatly impaired by extreme vasoconstriction. Their clinical use, however, is still *sub judice*.

3. Immobilization of fractures is an important measure, preventing further trauma at the fracture site.

4. The administration of oxygen is beneficial in cases complicated by cardiopulmonary disease or injury, and during anesthesia.

5. Apprehension, pain, and fatigue must be allayed because they may induce vasodilatation. Morphine, judiciously used, is the drug of choice.

that the amount of blood shifted from the lower parts of the body to its center improves the vasomotor status. The shock position may be inadvisable in patients with cerebral or cardiopulmonary complications.

8 The early use of wide-spectrum antibiotics in large amounts in the presence of infection or contaminated wounds is of paramount importance.

9. ACTH and cortisone have special value in the treatment of shock in the following circumstances:

- a Operations involving removal or interference with secretion of pituitary and adrenal glands, e.g., Cushing's disease
- b Operations on patients who have been under treatment with cortisone for a long time
- c Addison's disease

In one type of case the sudden withdrawal of adrenocortical secretion may precipitate collapse. In the other type, patients whose adrenocortical activity has been suppressed by long, continuous treatment cannot respond to the sudden increased demand of the added stress of operation. Peripheral circulatory collapse and hypoglycemia result. In both cases, treatment consists of giving cortisone in adequate doses 100-200 mg. daily before and after operation, gradually reducing the dosage in the postoperative period. During operation it may be necessary to treat with intravenous cortisone. Blood transfusions and vasoconstrictors are also indicated.

The occurrence of collapse in patients with adrenocortical insufficiency when infection or trauma supervenes is treated with cortisone intramuscularly and intravenously. As already mentioned above, shock may also occur in patients under long-term treatment with cortisone who develop infection or receive an injury or undergo an operation. Such an eventuality must be avoided in patients with arthritis, asthma, or dermatitis or in others receiving cortisone for long periods. Evidence of its use must be specifically sought in taking the history of such patients prior to operation. Under such circumstances, as well as during the course of any intervening illness, the cortisone should be increased. In all such cases when shock is either present or may be anticipated, it is well to support the circulation by using norepinephrine or other vasoconstrictor.

Fig 18—Infection and shock. This case illustrates the importance of adequate treatment of infection as well as shock which was due to peritonitis following perforation of a duodenal ulcer one week previously. At operation 1 liter of pus were found within the abdomen, which accounted for the hemoconcentration (Hgb 120%)

6 Body temperature should be maintained but the excessive application of heat, an effective vasodilator, by relaxing compensatory vasoconstriction may precipitate shock.

7 Because of vasomotor instability, the patient who is bleeding or already in shock should be moved as little as possible except for posturing in the head low position. Elevation of the foot of the bed in patients with a moderate reduction in blood volume causes a definite increase in blood pressure, indicating

and to give blood transfusions during the critical phases.

Chronically ill patients may not respond well to an added stress because of a relative adrenocortical insufficiency, and an operation may precipitate collapse. In such cases ACTH and cortisone should be used on an empiric basis along with transfusions and vasoconstrictors to restore the blood pressure.

Complications and Consequences

The consequences of *severe* or *untreated shock* are several. Some of the more serious of them are acute renal failure, myocardial infarction, cerebral thrombosis, and irreversible or delayed shock. Myocardial infarction and cerebral thrombosis are more likely to occur in the elderly and in individuals with coronary or cerebral arteriosclerosis.

Delayed shock is a term used to describe the fatal form in which, after restoration of normal blood pressure by transfusions following an initial period of severe or prolonged hypotension, the blood pressure steadily declines, and the patient dies even though the blood volume may be normal. The cause is unknown, but severe infection and massive hemorrhage inadequately treated either separately or in combination are important contributory factors.

The term *irreversible shock* has crept into clinical usage where it has no place. It belongs in the experimentalist's vocabulary where it means that shock has been produced in such a manner that precludes the animal's survival from hemorrhage. The term has often been used to describe therapeutic failure in patients who have been treated for shock. Its clinical usage should be discouraged, not only for the reasons just mentioned, but because it is dangerous since it may lead to the neglect of opportunity for effective therapy.

In conclusion, it is worth while to repeat that blood must be given as soon as possible after hemorrhage, and it must be given rapidly and in adequate amounts. The view that blood transfusion by raising the blood pressure may increase or cause a resumption of bleeding is entirely unfounded, and if transfusion is for this reason withheld, the results may be fatal. In cases of massive hemorrhage requiring large

amounts of blood to restore blood pressure to normal, inadequate amounts may be given for fear of overloading the circulation. Such fears are likewise unfounded if the level of the blood pressure is used as the guide for determining the amount of blood to be used. Only after the blood volume and blood pressure have been restored to normal is it likely that further transfusion will overload the circulation. When the normal blood volume as reflected by a normal blood pressure has been achieved and maintained, the need for rapid transfusion no longer exists. The transfusion may then be continued at a slower rate. Signs of increasing the blood volume beyond normal may be found by inspecting the neck veins for fullness and by auscultating the chest for rales at the bases. More deaths result from transfusion given "too little and too late" than from circulatory overloading.

The treatment of shock because of its emergency nature has been compared with the treatment of diabetic coma in that it is not enough to start treatment, write orders, and return later to see how the patient is progressing. There is probably no other condition that demands such resourcefulness, close supervision, and sense of urgency during the entire period of treatment. The effects of anoxia are so serious that in profound shock the period during which transfusion may be effective is often measured only in minutes, almost never in hours.

BLOOD TRANSFUSION

The recent advances in the recognition and treatment of shock and the development of blood banks and transfusion services have contributed greatly to the progress of surgery. They have become important factors both in the performance of operations and in the recovery from injuries in which the amount of blood lost may be considerable. Shock has been discussed in the preceding section.

Blood transfusion may be considered under five main headings:

1. Biochemical aspects
2. Immunologic aspects
3. Therapeutic aspects
4. Reactions
5. The blood bank and transfusion services

Biochemical Aspects

The constituents of whole blood which are of chief importance in transfusion therapy are the erythrocytes and the plasma. The solutions used for the preservation of blood have been designed for the best preservation of the erythrocytes without too great dilution of the whole blood mixture. The solution includes

Under the ordinary storage conditions of the blood bank, blood may be used up to three weeks following donation. Maximum benefit is obtained by the transfusion of fresh blood. The rate of loss of viability of erythrocytes in preserved blood is approximately 1% of the cells per day, but after three weeks they deteriorate more rapidly. Blood which has not been used by the end of this period is set aside

Fig 19—Blood transfusion apparatus with pressure connection for rapid intravenous or intra-arterial transfusion

sodium citrate as anticoagulant and dextrose as preservative. The proportion of whole blood to solution of anticoagulant and preservative in the average bottle of blood is approximately three parts whole blood to one part diluent. As an additional preservative measure, blood must be stored at a temperature of 4°C . Freezing and thawing destroy the erythrocytes

to permit the sedimentation of the cellular elements. The supernatant plasma is then drawn off and stored. The cells are discarded.

Plasma can now be separated at the various commercial and government-operated laboratories into several components, chiefly albumin, fibrinogen, and gamma globulin. The use of plasma as a blood substitute is diminishing be-

cause of (1) the development of plasma expanders, (2) certain dangers inherent in plasma infusion,* and (3) the waste of gamma globulin, fibrinogen, etc., when whole plasma is used for the treatment of shock.

Albumin is the most important constituent of plasma from the standpoint of colloid osmotic properties. Its administration provides a rapid method of treating shock because it quickly shifts extravascular fluid into the circulation. It must be used cautiously in patients suspected of suffering from dehydration as well as shock.

The other important plasma fraction used in rare cases of shock is fibrinogen. More and more cases of bleeding due to a coagulation defect resulting from hypofibrinogenemia are being reported. Fibrinogen administration is often the only means of restoring the fibrinogen level to normal and of correcting the coagulation defect in cases of hypofibrinogenemia. The diagnosis of hypofibrinogenemia must be considered in the presence of hemorrhage occurring in cases of metastatic carcinoma of the prostate and pancreas, severe liver disease, and toxemia. It is also to be suspected in severe hemorrhage occurring during major lung surgery. The chief conditions, however, in which it may occur are missed abortion, e.g., Rh isosensitization with a dead fetus, and premature separation of the placenta at term, e.g., abruptio placentae.

Clinically the condition should be suspected in obstetric patients, of the type just described, who continue to bleed from the vagina despite repeated transfusions of even freshly drawn blood and other measures usually employed to stop hemorrhage. The patient's blood can be tested for fibrinogenopenia by the following procedure:

- (1) Withdraw 3 ml of blood
- (2) Allow to stand for 5 minutes.
- (3) If no clot appears, the fibrinogen level is at a critically low level

*Blood may contain the virus of hepatitis. Pooled plasma prepared from several donations therefore increases the risk of transmission of the virus. Although plasma stored at room temperature for six months is said to be safe in this respect, there is the possibility that it may contain bacterial contaminants which produce a potent toxin in lethal amounts over such a long period.

Fibrinogen is now commercially available. Every maternity hospital should maintain an adequate stock for emergency use. Bleeding can usually be controlled by the infusion of 4 Gm. Since fibrinogen prepared from plasma, which may contain the hepatitis virus, carries the virus with it in an active state, it should not be used unless absolutely indicated.*

Platelets (and leukocytes) disintegrate rapidly in stored blood unless special measures are taken to preserve them intact. The anithemophilic and labile factors also disappear rapidly in stored blood or plasma. Prothrombin is fairly well maintained in bank blood during the first week of storage.

The treatment of shock due to hemorrhage resulting from deficient platelets has recently been improved by the introduction of methods for the preservation of platelets for transfusion. Even fresh blood drawn in ordinary bottles is said not to contain sufficient thrombocytes. Hemorrhage from thrombocytopenia is often uncontrollable by ordinary transfusions. If blood is drawn into plastic bags or glass containers coated with silicone, the platelets may be preserved long enough to effect cessation of bleeding in such cases if the blood is immediately transfused. A simple procedure used at the Royal Victoria Hospital is as follows:

- (1) The patient's blood is grouped
- (2) A blood sample is obtained from a donor of the same group as the patient
- (3) The donor's and patient's blood is cross-matched
- (4) If compatible, the donor is bled into a Fenwal plastic bag or a Baxter bottle coated with silicone
- (5) The patient is transfused immediately after the donation has been completed

The coagulation process and the hemorrhagic disorders and their treatment are summarized in Table 2.

The following cases illustrate the facts summarized in Table 2.

CASE 1. THROMBOCYTOPENIC PURPURA.—A 32-year-old woman was transferred to the Royal Victoria Hospital from another hospital for treatment of

*The prophylactic use of gamma globulin in cases where fibrinogen has been administered is recommended.

SHOCK AND BLOOD TRANSFUSION

TABLE 2

THE COAGULATION PROCESS		HEMORRHAGIC DISORDERS	TRANSFUSION TREATMENT
1 Platelets + AHG, PTA, PTC	Thromboplastin	Thrombocytopenic purpuras	Silicone blood

acute renal failure on April 13, 1957. On admission she was critically ill, febrile (102° F), dehydrated, with generalized tremors and purpura. The history revealed that on March 30 she had sustained a perforation of the uterus when an attempt was made to empty the uterus of a 4-month pregnancy. The following day laparotomy was performed, and the abdominal cavity was found to contain a dead fetus and about 4,000 ml of bloody fluid, which, together with the uterus, were removed. The laboratory findings on admission included NPN 221 mg %, platelets scanty, WBC, 45,000, urine specific gravity 1.020, albumin 1+, numerous RBC, occasional WBC, rare granular cast, volume 2,000 ml per 24 hours. The serum Na, K, Cl, and CO₂ were within normal limits. For the next few days the patient remained in a critical condition, with evidence of bleeding into the gastrointestinal tract. Treatment consisted of Chloromycetin, 500 mg b.i.d., for the peritonitis, maintenance of normal fluid and electrolyte balance, and the transfusion of platelet-rich blood and platelet concentrates. She gradually improved, and by May 1 the NPN had declined to 38 mg % and the platelets had become abundant. During this time she had received 9 bottles of platelet-preserved blood (500 ml each) and platelet concentrates prepared from 9 bottles of blood.

CASE 2 HEMOPHILIA.—A 10-year-old boy, known hemophilic, was transferred to the Montreal Neurological Institute January 18, 1957, from the Montreal Children's Hospital where he had been admitted January 16 following a fall the previous day. He was transfused with several units of plasma and transferred to the Montreal Neurological Institute because of developing paresis. At operation compression of the cord due to an epidural hematoma was found. The coagulation time was markedly prolonged on admission. He was transfused with 400 ml of fresh plasma and 3,000 ml of blood during the operation. Following operation he received daily infusion of fresh blood because of continuous oozing from the wound, hematuria, and epistaxis. Coagulation time throughout his stay in hospital remained prolonged and he developed a circulating anticoagulant.

At the time of discharge the wound had healed and there were no further hemorrhagic manifestations despite the prolonged coagulation time. During his hospitalization of 10 weeks he received 30 transfusions of fresh blood (500 ml each) plus 36 transfusions of fresh plasma (150 ml each).

CASE 3 HYPOPROTHROMBINEMIA.—A 71-year-old man was admitted on January 20, 1957, to the Royal Victoria Hospital with a history of jaundice of one month's duration. After investigation of liver function and coagulation studies, he was prepared for laparotomy. As his prothrombic activity was markedly impaired (25% of normal), he was treated with vitamin K and transfusion (1,000 ml) of fresh blood preoperatively. A stone in the common duct and a pathologic gall bladder were removed. Postoperatively he developed shock due to profuse hemorrhage and required 8 bottles of blood (4,000 ml). During the next few weeks his prothrombic activity averaged 40% of normal, and the deficiency was found to reside in the proconvertin fraction (stable factor). He was treated with 8 more transfusions of fresh blood before his discharge from hospital.

CASE 4 HYPOFIBRINOGENEMIA.—A 41-year-old woman, group O Rh negative, nonisensitized para, was admitted to the Royal Victoria Montreal Maternity Hospital bleeding from a placenta previa. After losing a small amount of blood during the afternoon she was delivered at 5:15 P.M. of a normal infant per vacuum with low forceps, the placenta followed at 5:55 P.M. At delivery there was a loss of approximately 600 ml of blood from the placental site controlled by manual pressure. She was transfused with 1,000 ml of blood. Fibrinogen was administered, bleeding continued, however. After transfusion of another 1,000 ml, it was noted that the clot in a specimen of blood had disappeared. Packing of the lower segment did not control the bleeding which was massive. Hypofibrinogenemia was diagnosed, and preparations for an immediate hysterectomy were made, during which time she was transfused with 2 Gm of fibrinogen and 1,000 ml of blood. An additional 1 Gm of fibrinogen and 2,000 ml of blood were transfused.

to control bleeding and maintain normal blood pressure. The following day blood studies revealed a hemoglobin of 58% and a reduced plasma volume as well. She was then transfused with 500 ml. of whole blood and 500 ml. of packed cells, an additional 1,000 ml. of whole blood being transfused several days later to restore the hemoglobin and blood volume to normal.

The use of *red cell suspensions*, or "*packed cells*" as they are commonly called, has proved valuable in the treatment of chronic anemia in patients with cardiac or renal disease in whom the volume of fluid administered must be restricted. This procedure also conserves plasma for, except in cases of shock or hypoproteinemia, whole blood is not usually needed in the treatment of chronic anemia. The method of preparation consists in allowing the red cells to sediment spontaneously or with the aid of centrifuging, drawing off the supernatant plasma, and transferring the cells to a separate container. If the blood has been collected in one of the dextrose preservative solutions, the cells may be stored in the sedimented state as long as whole blood. Their administration is the same as for whole blood after appropriate grouping and cross-matching.

The preparation of plasma and red cell suspensions demands the most careful technique and sterile precautions since these materials, which are excellent bacterial culture media, may be stored for a considerable period before being used. It is important to note that some pathogenic organisms whose toxins are lethal may continue to multiply in contaminated plasma even when stored at 4° C. If a transfusion for any reason has to be stopped, the same bottle of whole blood, plasma, red cell suspension, or any other intravenous solution should not be used again if more than an hour has elapsed between the first attempt and the next because of the danger of contamination.

Whole blood, plasma, or red cell suspension must always be administered with an intravenous set containing a *fine-mesh filter* to remove particulate matter or clots that may have formed.

Immunologic Aspects

The immunologic factors of clinical importance in blood transfusion are as follows:

1. The agglutinogens A and B
2. The Rh and related factors
3. Other rare factors

Of equal concern are the corresponding antibodies, the agglutinins anti-A, anti-B, anti-Rh, anti-Kell, anti-Duffy, etc.

The Landsteiner (or ABO) Blood Groups.—All individuals may be divided into four groups, depending on whether their erythrocytes contain either of the agglutinogens A or B, both, or neither of them. Agglutinins are present in the serum of an individual corresponding to the agglutinin which is absent from the erythrocytes of that individual as illustrated in Table 3.

TABLE 3
INTERNATIONAL (LANDSTEINER) NOMENCLATURE

NAME OF BLOOD GROUP	AGGLUTINOGEN IN ERYTHROCYTES	AGGLUTININ IN SERUM
AB	AB	Neither
A	A	Anti-B (beta)
B	B	Anti-A (alpha)
O	Neither	Anti-A and anti-B

In every transfusion it is the donor's erythrocytes that must be compatible with the recipient's, i.e., not agglutinated (clumped), by the agglutinins in the recipient's serum. As indicated in Table 4 Group O blood may be given to individuals of any group because O blood contains neither agglutinin A nor B. Persons belonging to Group AB may receive blood of any group because their serum does not contain either agglutinin anti-A or anti-B. With these two exceptions donor and recipient blood must belong to the same group to avoid agglutination, hemolysis, and the serious consequences of an incompatible transfusion reaction.

TABLE 4
INTERACTION OF THE 4 BLOOD GROUPS

CELLS	AB SERUM (NO AGGLUTININS)	A SERUM (ANTI-B AGGLUTININS)	B SERUM (ANTI-A AGGLUTININS)	O SERUM (ANTI-A AND B AGGLUTININS)
AB	-	+	+	+
A	-	-	+	+
B	-	+	-	+
O	-	-	-	-

+ = agglutination

- = no agglutination

Laboratory Technique.—Students and interns should be familiar with the technique of grouping and cross-matching blood because of the frequent urgent need for transfusion in the prevention and treatment of shock. The test for determining to which of the four blood groups a patient or donor belongs is performed as follows:

Two drops of citrated blood are added to approximately 5 ml. of normal saline A drop of the saline cell suspension is added to each of two serologic tubes. To one tube add a drop of anti-A grouping serum; to the other tube add a drop of anti-B grouping serum. Centrifuge at 1,000 rpm for two minutes. Examine for agglutination with the aid of a microscope. Reference to Table 4 will show how any unknown blood can be typed by noting the reaction of the erythrocytes with the anti-A and anti-B serums.

The technique of cross-matching is as follows. To a serologic tube marked "major" add a drop of a saline suspension of donor's cells and a drop of recipient's serum or plasma. To another tube marked "minor" add a drop of a saline suspension of recipient's cells and a drop of donor's plasma. Centrifuge and examine for agglutination.

Clumping of the cells in the *major cross-match* indicates that the bloods are incompatible and that the donor blood must not be given.

Agglutination in the *minor cross-match* may occur if (1) Group O donor blood is being tested against the blood of A, B, or AB recipient; (2) Group AB recipient blood is being tested against the blood of an A, B, or O donor. Only in these two instances may agglutination in the *minor cross-match* be disregarded because otherwise it indicates that the donor and recipient blood are incompatible.

The RH Blood Groups.—There is a group of six related factors which has a special importance in obstetrics. This group, known as the Rh Hr or CDE-cde system, and its incidence in the white race are shown in Table 5.

The original Rh factor is the most antigenic. The terms Rh positive and Rh negative therefore refer to the presence or absence of Rh, (D).

TABLE 5

NOMENCLATURE		PER CENT PRESENT	PER CENT ABSENT
WIENER	FISHER-RACE		
Anti-Rh ₀	Anti-D	85	15
Anti-Hr _a	Anti-d	63	37
Anti-rh'	Anti-C	70	30
Anti-hr'	Anti-c	60	20
Anti-rh''	Anti-E	30	70
Anti-hr''	Anti-e	97	3

Although the anti-Rh agglutinins are not normally present in the serum, they may be acquired during pregnancy or after transfusion of blood of a different Rh type from that of the recipient. Isoimmunization to D is frequent, to c and E much less frequent, and to d, C, and e very rare. D is involved in approximately 93% of cases of hemolytic disease of the newborn. Although rare, immunization of Rh-positive individuals may occur; in such instances it usually involves c.

The anti-Rh agglutinins (Rh antibodies) combine with the Rh agglutinogens of the fetal erythrocytes and cause hemolysis, a condition known as *hemolytic disease of the newborn* or *erythroblastosis fetalis*. Nothing happens to the mother because there are no Rh agglutinogens in her erythrocytes to combine with the antibodies in her serum. If, however, she receives a transfusion of Rh-positive blood during pregnancy or in the puerperium, the transfused erythrocytes combine with the antibodies in her circulation to cause a transfusion reaction which may be fatal.

Transfusions of Rh-positive blood into Rh-negative individuals may result also in isoimmunization, and a severe reaction during a subsequent transfusion of Rh-positive blood, or as in the example of a mating cited above, they may initiate the process of isoimmunization even before the woman becomes pregnant for the first time. It is important, therefore, to test for the Rh in addition to the ABO factors and to use only blood of a suitable type. This is especially important in pregnancy and the puerperium because of the possibility of the presence of circulating Rh antibodies, and also in all female patients from infancy to the end of the childbearing period to prevent Rh isoimmunization by transfusion.

Laboratory Technique.—The simplest and quickest test for the determination of the Rh type is the open slide method. Place on a glass

source of error in cross-matching. Such an error may be avoided by the prompt examination of the cross-match.

Therapeutic Aspects

The treatment of shock with whole blood and plasma, as well as the use of plasma in various other conditions, and the use of red cell suspensions in chronic anemia have already been described in detail in this and the preceding section.

The use of *blood substitutes*, however, deserves special mention. It is now customary to refer to the substances which increase blood volume as *plasma expanders*, *extenders*, or *augmenters*. There is no substitute for blood

massive or prolonged hemorrhage, e.g., gastrointestinal bleeding, in which condition blood in large amounts is required.

In many cases a substitute alone will prevent or counteract shock. Most blood transfusions are given for operations requiring from 500 to 1,000 ml. of blood replacement. It is in this type of case that the substitute has an important role as blood-sparing agent.

Because the expanders have certain disadvantages, the search for an ideal one continues. It is centered on a fraction of human plasma containing albumin and the alpha and beta globulins and is free of hepatitis virus. Gelatin gels at room temperature. Polyvinyl pyrrolidone (PVP) is not metabolized and

Fig 21—Plasma expanders in shock. This shows the value of the plasma expanders dextran and PVP in the treatment and prevention of shock in two common situations where ordinarily 2 or 3 bottles of blood are used

when hemorrhage is massive. In cases, however, where amounts ranging from 500 to 1,500 ml of blood are ordinarily used, plasma expanders may be substituted for blood. In emergency situations their use is often a life-saving measure during the time necessary to start a transfusion. Their use in these circumstances justifies their being called blood substitutes.

In most hospitals blood is chronically in short supply. If the extenders were used in cases where ordinarily one or two bottles of blood are administered during operation, more blood would be available for the treatment of

consequently that which is not excreted stored in the reticuloendothelial system. Dextran interferes with the coagulation mechanism and may cause bleeding from the operative site. Since dextran in amounts of more than 1,000 ml has been shown to cause a bleeding tendency, it should not be used in patients with coagulation defects (thrombocytopenia, hypoprothrombinemia, etc.) or in those receiving anticoagulant therapy. Despite these limitations, however, they are valuable therapeutic agents when used in the recommended amounts, in properly selected cases, and with their disadvantages in mind.

Transfusion Reactions

The incidence of transfusion reactions and their occurrence despite the utmost care in the grouping, cross-matching, and transfusion of blood afford a constant reminder that transfusion itself may be considered a major surgical procedure and should be undertaken only when definite indications for such therapy exist. The least serious of all is the so-called allergic reaction, although usually no allergic basis can be found in either the donor or recipient involved. The usual manifestation is urticaria, and the treatment is symptomatic.

Pyrogenic reactions are the most frequent of all transfusion complications. They are caused by pyrogens which are the polysaccharide fraction of endogenous substances of bacterial lysis present in transfusion equipment which has not been properly cleaned and autoclaved. The use of disposable donor and transfusion sets, guaranteed pyrogen-free by the dispenser, tends to reduce the incidence of such reactions. The symptoms are chill, increased temperature and pulse, restlessness, dyspnea, and pains in the chest and lumbar region. In a severe pyrogenic reaction there may be circulatory collapse and even death. The treatment consists of immediately stopping the transfusion and the application of supportive measures. Since the symptoms just described are also those of an incompatible transfusion, all reactions following the transfusion of whole blood or red cell suspensions should be regarded as being due to incompatibility until proved otherwise.

The causes of an incompatible or hemolytic reaction usually are attributable to technical or clerical errors in the laboratory or to carelessness on the part of those responsible for administering the blood. Because of the possibility of error in grouping or labelling blood, every transfusion of whole blood or red cell suspension should be cross-matched with the patient's blood before being given. This procedure detects such errors and is an additional safeguard in the prevention of reactions. Blood transfusion in many instances is lifesaving, but it can also be fatal. Constant care must be exercised in order to avoid such accidents.

The symptoms of an incompatible transfusion are those already described, plus the

signs of hemoglobinemia and hemoglobinuria, followed later by jaundice, oliguria, and, in fatal cases, death in uremia. Since the earliest manifestations of a hemolytic transfusion are usually those complained of by the patient, such as a feeling of chilliness, pains in the back, etc., extra care must be taken in giving transfusions to those under general anesthesia or otherwise unconscious. Excluding sudden fatality at the onset of the reaction, renal involvement is the cause of serious consequences.

The pathogenesis of the renal damage resulting in the condition known as *lower nephron nephrosis* is not entirely understood. It is doubtful whether hemolysis alone causes damage. Hemoglobinemias and hemoglobinurias are frequently observed in such conditions as the paroxysmal hemoglobinurias without causing renal insufficiency. The various factors involved in the renal damage may be summarized as lowered blood pressure, vasoconstriction of renal vessels, reduced renal blood flow, and the secretion of large amounts of hemoglobin or its derivatives in an acid urine. Morphologically the main alterations in the kidney involve the nephron where degeneration and necrosis of the tubular epithelium occur with heme casts in the distal segments and collecting tubules.

The treatment may be divided into two phases. In the first or immediate phase, on the first indication of a reaction as shown by the appearance of any of the above-mentioned symptoms, proceed immediately as follows:

1. Stop the transfusion.
2. Obtain a sample of the donor's blood and send it to the laboratory with a specimen of the patient's blood for regrouping and cross-matching and for examination for hemolysis.
3. Give the patient sodium lactate intravenously to render the urine alkaline as soon as possible.
4. Give glucose intravenously to provide fluid for diuresis.
5. Record the 24-hour fluid intake and output, examining the first specimen for hemoglobinuria.
6. Apply heat to the costolumbar regions for reflex relief of renal vasoconstriction.

During the second phase, treatment is directed toward maintaining a balance between fluid intake and output and toward preserving the acid-base equilibrium until renal function returns to normal. Until such time it is important not to force fluids, since pulmonary edema may develop. The use of the artificial kidney or other dialyzing mechanism should be considered in cases in which there is a gradually rising blood NPN and a decreasing urine output and specific gravity. The products of uremia are thereby removed during the period in which reparative processes may be proceeding in the damaged kidneys.

Other Complications.—

Jaundice—

Pretransfusion hemolysis. The least important in its clinical implications is that due to hemolysis of the donor cells either before or immediately after transfusion. The hemolysis is due to the early death of the cells because of improper storage or handling of blood, i.e., their life span has been so shortened that the cells are moribund when they are transfused. Blood is taken out of the bank to the wards or operating theater. It may be left standing at room temperature for several hours and then returned unused. The same blood may again be cross-matched and taken out for another patient. If this sort of thing happens two or three times, and the blood has not been properly cared for, the red cells reach senility earlier than the date of obsolescence stamped on the bottle. When such blood is transfused, massive hemolysis and jaundice may occur. There are usually no other manifestations such as precede the appearance of jaundice in the next type to be discussed. The prevention of this complication is the responsibility of everyone who orders a blood transfusion or handles a bottle of blood.

Hemolysis after transfusion. By far the most important of the causes of jaundice following transfusion is known as the hemolytic or incompatible transfusion reaction which has already been discussed.

Homologous serum jaundice. Finally, the third cause of jaundice is not a hemolytic process but a hepatitis which is caused by a virus transmitted in the blood or plasma of

the donor. Homologous serum jaundice may be differentiated from the preceding types by its late appearance at an average of 60 days following transfusion and by the various tests used to distinguish between hemolytic and nonhemolytic jaundice. Although the morbidity is extremely low, the mortality is high.

Embolism.—Embolism caused by the introduction of air in the transfusion should never occur. The use of specially prepared transfusion sets containing fine-mesh filters to remove particulate matter which might be the cause of embolism has already been emphasized.

Citrate Intoxication.—There is no evidence that, even in massive transfusions of 5-10 liters given over a short period of time, the citrate in the transfused blood or plasma has any toxic effect or causes any change in the coagulation time of the recipient's blood. The citrate radicle is rapidly removed from the circulation, oxidized, and excreted.

Although citrate is nontoxic, by reason of its calcium-binding capacity which renders it an anticoagulant in vitro as shown in Table 2, it may become harmful in certain situations. Exchange transfusion in the treatment of hemolytic disease is supplemented by the intramuscular injection of calcium gluconate if the blood is collected into citrate. There is an increasing tendency, however, to collect blood into heparin for exchange transfusion.

In operations on the heart especially, but also in others such as artificial renal dialysis in which extracorporeal circulation is necessary, heparinized blood is required because of the danger of citrate reducing the level of available calcium, thus leading to increased cardiac irritability, ventricular fibrillation, and standstill.

Heparinized blood may itself be hazardous. Although it keeps the blood fluid, it is a poor anticoagulant, allowing clotting to proceed in vitro as shown in a few hours by a decreased content of the various coagulation factors (platelets, prothrombin, fibrinogen, etc.) in bank blood. Its use in large amounts may be followed by generalized postoperative hemorrhage.

Pulmonary Edema.—The sodium radical may not be excreted rapidly. Its water retaining properties, especially when large amounts of

blood are transfused, may contribute to the development of edema. In such transfusions, furthermore, the amount of sodium citrate may assume significant proportions in patients with cardiac or renal disease. For example, since the ratio of blood to diluent is of the order of 3:1, in a transfusion of 4,000 ml there will be 1,000 ml of diluent, containing 17 Gm sodium citrate. It is important, therefore, to use sparingly other intravenous solutions, especially saline (unless specific indications for their use are present), so as to avoid circulatory overloading and pulmonary edema in patients with chronic anemia complicated by cardiovascular or renal disease. In the treatment of pulmonary edema, the performance of a phlebotomy is expedited by the use of blood donor equipment if the donor bottle is of the type that contains a vacuum.

The Blood Bank and Transfusion Services

The blood bank has become established as an integral part of the hospital. There are, however, other transfusion services organized on a community or regional basis, and the various Red Cross societies have developed plans for national blood transfusion services which are in operation in Canada, Great Britain, and the United States. The purpose of both types of services is the same, namely, the provision of adequate amounts of whole blood and plasma properly prepared for immediate transfusion.

Fresh blood contains the maximum of all components of donor blood and is as effective as in a direct transfusion. *Stored blood*, i.e., blood collected in sodium citrate solution only and refrigerated, may be used up to five days following donation, since degenerative changes develop rapidly in the erythrocytes if no preservative is added. When dextrose is added to the blood-citrate mixture to impede the rate of destruction of the erythrocytes, the resultant product is known as *preserved blood*.

Blood is obtained from healthy donors, male and female, between the ages of 18 and 65.

Approximately 350 ml of blood, under sterile precautions, are withdrawn into a bottle containing a volume of 125 ml. of a solution of sodium citrate and dextrose. At the same

time enough additional blood is taken for filling two tubes, one for serologic testing for syphilis, the other to be used for grouping, typing, and cross-matching. The blood is immediately refrigerated. When it has been grouped for the ABO factors and Rh typed, and the test for syphilis is negative, the blood is properly labelled and ready for use. Upon receipt of a requisition for blood transfusion, the accompanying sample of patient's blood is grouped and typed. Donor blood corresponding to the recipient's in respect of the factors ABO and Rh is cross-matched with the patient's and, if found compatible, is marked with the patient's full name, age, sex, ward, and service for proper identification to avoid its being given to the wrong patient. It is then delivered to the ward or operating room or is kept in a reserve compartment of the refrigerator until needed.

All of the above procedures are carried out by the blood bank staff whose grave responsibility in their proper performance is almost unique in medicine. The results of most laboratory tests are used to corroborate a clinical diagnosis, and any discrepancy between the clinical and laboratory findings may be checked by repeating the tests before the treatment is instituted. An error in technique, interpretation, or labelling by the blood bank may result in a serious or even fatal transfusion reaction.

Transfusion has entered a new era. In the beginning, as it became clear that surgical shock is due to hemorrhage, blood banks were established for its prevention and treatment. The next decade was characterized by advances in immunohematology and their application to the prevention of transfusion reactions and the management of hemolytic diseases of the newborn.

At the present time the responsibilities of the blood bank have been augmented by advances in our understanding of the coagulation disorders, the availability of blood and plasma fractions and the recognition of the specific indications for their use, and the ever-increasing number of operations requiring massive, fresh or heparinized blood transfusion.

The responsibility for the direction of a blood bank may be assigned to an anesthetist,

a bacteriologist, pathologist, physician, or surgeon. Blood transfusion, because of its many aspects and their rapid development over the past few years, has itself become a specialty. The functions of the director of a transfusion service should include not only the establishment and maintenance of the proper technical and administrative procedures but, also of equal importance, certain other activities. These include the provision of consultative services in all aspects of blood transfusion therapy and instruction of students and interns in the early recognition of shock, its treatment, and research in the problems related to shock and blood transfusion

Chapter 5

Preoperative and Postoperative Care

James F. Hopkirk, MD, and Richard C Long, MD

PREOPERATIVE MANAGEMENT

Assessment of the Surgical Patient as an Operative Risk

For the achievement of successful surgical treatment, the surgeon must make not only an exact diagnosis but also carefully plan and execute the operative procedure. This procedure must be carried out without untoward incidents which might lead to the death of the patient or to an unnecessary number of complications. The goal of each hospital admission and surgical procedure must be the early return of maximal possible function of the patient. This end can be gained only by a very careful preoperative appraisal of the patient, not so much in regard to the operative risk, but as to how much the entire phase of hospital treatment will either favorably or adversely affect him.

One of the most important phases of the preoperative and postoperative care is the development of an accurate medical record which must include a painstaking case history and physical examination, a preliminary working diagnosis, a graphic description of the operative procedure, detailed notes of the patient's progress in hospital, medications, complications, the success of the therapeutic procedure, and a well-considered final diagnosis.

Patients may be placed into two large categories in respect to their ability to withstand operative procedures:

1. Good risk
2. Poor risk

The good-risk patient is one who comes for the treatment of some surgical condition which has caused little or no systemic effect and has no accompanying disease or group of diseases, e.g., uncomplicated hernia.

The poor-risk patient is one who presents himself with disordered bodily functions which have been caused by the surgical condition for which he seeks relief, or by other concomitant disease or diseases, e.g., hernia with strangulation where more extensive surgery may be necessary.

It is difficult to categorize each patient. A superficial appearance of reasonably good health is often misleading, and more complete physical or laboratory examination may place this patient in the poor-risk category.

Many factors affect the assessment of the patient as an operative risk.

1. **The Adjustment of the Individual.**—An important consideration is the individual's adjustment to his disease, to his attending physician or surgeon, and to the hospital wards and personnel.

2. **Age.**—Infants and young children constitute individual physiologic and metabolic problems. They are very prone to develop infection and require special operative techniques. Developmental anomalies which are usually first noticed in this age group will frequently affect the planning and execution of an operative procedure. The elderly patient also constitutes a special problem. He reacts

less favorably to the trauma of operation, his nutrition is frequently poor, and he may have accompanying cardiovascular, renal, or respiratory disease which necessitates a careful choice of anesthesia and sedation.

3. Psychological Status.—It is important that the patient be carefully prepared as to the outcome of any operative procedure. An intimate patient-surgeon relationship is most important in all types of surgery. This is most essential in the handling of a patient with, for example, ulcerative colitis, for whom a permanent ileostomy will be required, or one with carcinoma of the rectum who will have a permanent abdominal colostomy.

4. Degree of Obesity.—The obese patient is always a poor surgical risk. Technical procedures are much more difficult in such cases, wound healing tends to be delayed, and the wounds are more prone to become infected.

5. Nutritional Status.—The recognition, prevention, and treatment of nutritional deficiencies are important because many surgical conditions may be improved by careful nutritional therapy, and many postoperative complications may be prevented by an adequate preoperative diet.

The assessment of the nutritional status of the surgical patient is made by a careful examination of the patient's dietary history, his weight history, the condition of his tissues, his response to adequate dietary therapy, and by such laboratory aids as estimation of the serum protein levels and the albumin-globulin ratio.

6. Cardiovascular Status.—The status of the cardiovascular system must be carefully assessed and particular attention paid to the history of recent cardiac accident, decreased exercise tolerance, presence of cardiac failure, or severe congenital heart disease. Hypertension necessitates that special steps be taken in the anesthetic management to prevent a hypotensive episode.

7. Status of the Liver.—The liver is frequently adversely affected by nutritional disorders and dietary deficiencies. All surgical patients must have a sufficient protein and carbohydrate intake because adequate storage of liver protein and glycogen is required to prevent untoward accidents, such as the so-

called liver failure which occurs sometimes following surgical procedures.

An attempt can be made to evaluate functional status of the liver by a careful study of diet and weight and by the response to adequate nutritional measure. For example, the disappearance of edema or following high protein intake. In addition, use of various liver function tests can give valuable information. (See Chapter 19, and Portal Hypertension.)

8. Status of the Urinary Tract.—The function of the kidney must at all times be fully assessed, as impaired renal function markedly increases the incidence of postoperative complications and possibly may even to the death of the patient. An adequate outflow of satisfactory specific gravity is one of the best indications of good renal function.

An estimate of the urinary function may be made by an inquiry into the following factors:

- A The urinary history, e.g., nephritis, prostatic disease.
- B Renal function tests which include:
 - (1) urinalysis
 - (2) urine concentration tests, Mosenthal
 - (3) renal excretion tests, e.g., phenolphthalein excretion
 - (4) blood serum estimations, e.g., serum nonprotein nitrogen

9. Hematologic Status.—The anemic patient does not withstand operation well. If ill equipped to tolerate operative blood loss and is frequently in a state of malnutrition. It is therefore essential that the hemoglobin and red blood cells be within reasonably normal range prior to surgery, whether the surgical procedure is of an emergency or of elective nature. A knowledge of the level of the white blood cell count is important as occasion agranulocytosis or leukemia may present.

10. The Operation Itself.—The magnitude and type of operation must be considered when assessing the risk to the individual patient. A poor-risk patient, for example, might withstand a minor procedure, whereas a major operation could be fatal.

The Attending Surgeon's Visit—It is the duty of the attending surgeon to take the time

to explain to the patient in simple language the stages in preoperative management which have been ordered, to describe in some manner the operative procedure and the anesthetic to be used, and to indicate to the best of his ability what the patient may expect in the immediate postoperative period.

Nutrition

The recognition, prevention, and treatment of nutritional deficiencies are important because many surgical conditions may be improved by adequate nutritional therapy, and many postoperative complications may be prevented by careful attention to diet.

The normal individual requires 2,500-3,000 calories per day, and the diet must include sufficient protein, carbohydrate, fat, vitamins, and minerals. Nutritional deficiencies in surgical patients are relatively common and arise as a result of

1. Inadequate intake (starvation, ulcer diet, parenteral feedings)
2. Increased requirements (hyperthyroidism, pregnancy, increased muscular activity)
3. Impaired absorption or excess loss (pyloric stenosis, esophageal obstruction, vomiting, diarrhea, intestinal fistula)
4. Defective utilization (diabetes)

Such deficiencies must be corrected before any major surgical procedure is contemplated.

Caloric Requirements.—An adequate caloric intake is necessary to prevent actual or partial starvation. An inadequate caloric intake results in starvation of the tissues with resultant tissue breakdown and an increase in nitrogen excretion.

The administration of a high caloric diet in a patient with a good appetite can readily be accomplished by an oral intake of high caloric foods supplemented if necessary by high caloric, high protein milk shakes. If the patient's condition is such that oral feeding is impossible or restricted, the problem becomes increasingly difficult. An attempt to supply the full caloric requirements with isotonic intravenous glucose alone is unsatisfactory, as such a large volume of fluids must be given. Intravenous fat if available, however, offers a

means of providing such a high caloric intake without the difficulties which arise when glucose solutions are used.

Tube feeding with carbohydrate, protein, and fat in the correct proportions may also be used at times to ensure the necessary number of calories.

Protein.—The body proteins are compounds of amino acids and form a proportion of all living tissues. Ingested proteins are hydrolyzed into their constituent amino acids, which are then absorbed from the small intestine.

The plasma proteins consist of three fractions.

1. *Albumin*, which is chiefly responsible for maintaining osmotic pressure
2. *Globulin*, which consists of immune substances, antibodies, and agglutinins
3. *Fibrinogen*, which is essential for the clotting of blood

The normal level of the plasma proteins is 7 Gm/100 ml. with an albumin/globulin ratio of 1.5/1. The serum protein, while useful as a guide, is not a true indication of the total body protein, for depleted reserve stores of protein in the tissues may be present with a normal level in the circulating blood. Gross edema usually occurs when the serum albumin is less than 3.0 Gm/100 ml. However, the degree of the edema may be modified by the presence of anemia and by disturbances in electrolyte balance.

There are five main causes of protein deficiency:

1. Insufficient intake of protein to meet the demands of the body; e.g., anorexia, obstruction of the upper alimentary tract, and vomiting
2. Inadequate digestion or absorption of protein; e.g., in chronic gastrointestinal disease, gastrojejunocolic fistula, abnormalities in secretion of the stomach or pancreas
3. Impaired protein synthesis; e.g., in severe liver disease
4. Excessive protein loss; e.g., in kidney disease, burns, ascites, ulcerative colitis, or empyema
5. Increased protein catabolism; e.g., in association with fever, hyperthyroidism, opera-

tive procedures, severe trauma, malignant diseases, or extensive burns

The effects of such protein deficiency may cause serious complications in the surgical patient. Every operation increases nitrogen catabolism with a resultant demand on protein reserves and usually results in a temporary negative nitrogen balance. Protein depletion is increased by hemorrhage, serum loss, and suppuration. Inadequate protein intake is associated with delay in wound healing, wound disruption, and chronic indolent ulcers. Hypoproteinemia aggravates the tendency to edema following gastrointestinal operations with resultant obstruction of the anastomotic stoma. The liver, if deficient in protein and especially if low in methionine and cystine, is very susceptible to toxic agents and to the effects of operation

Correction of Protein Deficiency—The best way to supply the caloric and protein requirements of a patient is to provide an adequate oral intake. Whole foods, rather than protein hydrolysates, should be used. A diet containing 1 Gm of protein per kilogram of body weight is adequate for the average patient, although for short periods this amount may be reduced if sufficient carbohydrate is added. If there has been extensive trauma or severe infection, much larger quantities of protein, up to 300 Gm/day, may be required. There is evidence that a high protein diet given for a period prior to operation may increase the protein reserves of the body and so compensate for nitrogen loss in the postoperative period.

Protein deficiency in the presence of anemia presents a special problem. If the body is in need of both hemoglobin and plasma protein, the formation of hemoglobin is favored. It is therefore most important that existing anemia should be corrected by adequate transfusions of whole blood in protein-deficient patients.

It is essential that the patient be placed in positive nitrogen balance and that the plasma protein be restored to normal levels before a major surgical procedure is undertaken.

When normal oral feedings are contraindicated, or when only small amounts can be given by this route, other methods must be

utilized, e.g., tube feedings with protein hydrolysates or other protein fluids, jejunostomy or gastrostomy feeding, or intravenous feeding

Intravenous administration of whole blood, plasma, serum albumin, and protein hydrolysates can be used in tiding over a patient for a short time when oral intake is impossible or inadequate. Whole blood and blood derivatives are impractical for long-term use. They are expensive, the supply is limited, and the increased blood volume which follows their use may lead to cardiac embarrassment. Protein hydrolysates, reinforced with glucose, can maintain a positive nitrogen balance if given in sufficient amounts. In the usual protein hydrolysate solution, there are somewhat less than 50 Gm. of protein per 1,000 ml, and there is considerable evidence to show that such hydrolysates are only partially utilized by the body. With the preparations available there is a high incidence of reactions: nausea, vomiting, fever, and headache. Solutions of pure amino acids are of greater value and are capable of providing adequate protein requirements with minimal or no side effects. However, in the presence of marked protein deficiency, it is impossible to supply sufficient protein by this method.

Vitamins and Minerals—The administration of additional vitamins and minerals is unnecessary if the patient is taking a full and well-balanced diet. In debilitated patients and in those for whom parenteral feedings are required, vitamin supplements must be provided. Combustion of carbohydrate greatly increases the requirement for the vitamin B complex, and this should be given parenterally to all patients who are receiving intravenous glucose feedings. Vitamin C must also be given as its lack may lead to delay in wound healing. In the jaundiced patient or in one with advanced liver disease, parenteral vitamin K must be used.

Body Fluid and Electrolytes

Fluid and electrolyte derangements are extremely common in the surgical patient. Even minor operations which require some degree of immobilization, or restriction of the intake of food and water, have a slight, although perhaps hardly perceptible, effect on the body

However, operations which require general anesthesia can, through toxic effects, vomiting, and the development of the alarm reaction, cause a metabolic disturbance which can be profound. This disturbance is due both to a deficit in water and electrolytes and a defect in the normal pattern of these substances. This defect may not be great and, indeed, is frequently unnoticed. However, the surgeon must anticipate the possibility of any disturbance in the fluid-electrolyte pattern and treat it in such a manner as to avoid a major physiologic breakdown.

Severe fluid and electrolyte derangements also occur as a result of an acute disease process. These derangements must receive early and intelligent restorative therapy in order that the underlying disease may be successfully treated.

In order to formulate a plan of successful fluid and electrolyte therapy, the type of imbalance leading to the dehydration must first be established, and the magnitude of the defect must be estimated, following which the correct treatment may be planned and then executed.

The body fluids make up, on the average, 60% of the total body weight. This figure varies with the sex, age, and bodily habitus of the patient. In the newborn infant, 77% of the body is water. This percentage gradually falls so that by the age of 9 years, it stabilizes at the average for the adult. In the adult, there is a distinct sexual difference, the male having 17% more body water than does the female.

The body water is contained in two great compartments. The intracellular compartment contains about two thirds and the extracellular compartment about one third of the total body water. The extracellular fluid is divided into the *interstitial* and *intravascular* fluids which comprise 15% and 5%, respectively, of the total body fluid—three fourths (10.5 L.) and one fourth (3.5 L.) of the extracellular fluid.

The dominant intracellular ions are the cation potassium (K^+) and the anion phosphorus expressed as phosphate (PO_4^-). The dominant extracellular ions are the cation sodium (Na^+) and the anion chloride (Cl^-).

However, both the intracellular and extracellular compartments contain appreciable amounts of all ions.

1. The Extracellular Compartment

Cations

Sodium.—The concentration of sodium in the extracellular fluid is 142 mEq/L. There are, on the average, 65 Gm. of sodium in the body, of which 38 Gm. are in the extracellular compartments, 6 Gm. within the cells, and 21 Gm. in the bone; this exists as sodium chloride. This body sodium is divided into two portions: (1) the *exchangeable sodium* which is physiologically active, and (2) the *inert sodium*, contained in the bones, which is physiologically inactive. Under certain circumstances, e.g., in severe dehydration, a portion of this inert sodium may be made available for bodily reactions.

The sodium ion makes up over 90% of the total base and is the principal factor controlling osmotic pressure in the extracellular fluid. The other cations (Ca, Mg, and K) have little effect on fluid shifts, although they have great physiologic importance.

The concentration of extracellular sodium is chiefly maintained by (1) the sodium intake of the individual, and (2) the selective secretory action of the kidney. In times of sodium deficiency, the kidney tubules conserve body sodium so efficiently that virtually none is lost in the urine. In times of sodium abundance, excess sodium is freely secreted by the kidney. Also a decrease in serum sodium concentration will indicate a loss of fluid in order to re-establish the normal serum levels. An increase in sodium concentration stimulates water retention, thus diluting the sodium ion back to its normal serum level.

The average intake of sodium is 6 Gm. per day, varying slightly with the individual's taste and habits. Sodium is lost from the body in urine and sweat. The urinary sodium averages about 110 mEq/day. Insensible perspiration is essentially electrolyte-free, but if perceptible sweating occurs there is electrolyte loss.

There is a continuous movement of sodium in and out of the cells in health and disease. The concentration of the intracellular sodium

varies directly with the pH of the extracellular fluid. In *alkalosis* (pH over 7.45) the intracellular sodium is elevated, and the intracellular potassium is decreased. The reverse is true in *acidosis*, whatever the etiology may be. The plasma concentration of the sodium is in equilibrium with that of the interstitial fluid so that routine analysis of the interstitial fluid as well. In cases of potassium deficiency, sodium enters the cells in large quantities in order to preserve the cells' isotonicity. However, the newly shifted intracellular sodium does not function with the same biologic efficiency as does the normally occurring intracellular ion potassium.

Potassium.—Normally the concentration of extracellular potassium varies between 3.5-5.5 mEq/L., comprising about 2% of the total body potassium. Although the daily requirements of potassium are not known, the normal diet contains more than a sufficient amount for the body needs. It is normally excreted almost entirely in the urine at the rate of 30-50 mEq/day (1.45-1.95 Gm). In contradistinction to its control over sodium, the kidney has no power to conserve potassium in times of potassium deficiency, so that potassium continues to be lost at a constant rate providing the urinary output is maintained. The concentration of potassium in the extracellular fluid does not necessarily reflect the potassium concentration within the cell although, as with sodium, it indicates the level in the interstitial fluid.

Calcium.—The normal serum calcium is 4.5-5.8 mEq/L. (9-11.5 mg/100 ml.) This level is slightly, if at all, affected by the daily calcium intake. An excess is excreted by the kidneys, and any defect is made up by a shift of calcium from the bones to the extracellular fluid. The serum calcium level is largely regulated by the parathyroid hormone. Occasionally calcium deficiency will accompany other electrolyte imbalance, e.g., respiratory alkalosis.

Magnesium.—The normal serum magnesium is 1.4-2.4 mEq/L., and the total body content of magnesium is approximately 19 Gm. It is excreted in the feces (60%) and urine (40%). Most of the magnesium is contained in the intracellular water and in the bones.

Magnesium is an essential coenzyme in carbohydrate and protein metabolism and has an effect on neuromuscular irritability.

Anions

Chloride.—The normal serum chloride concentration is 103 mEq/L., and the total body content of chloride is approximately 8.5 Gm. The average intake of chloride, ingested chiefly as sodium chloride, varies from 69-260 mEq/day (2.4-9.2 Gm). The concentration of extracellular chloride varies inversely with the bicarbonate level. A loss of chloride from the body is met by an increase in bicarbonate so that there is no accompanying loss of water. This is in contradistinction to sodium loss, where no compensating factor exists and where water loss occurs. A deficit of the chloride ion leads to a loss of potassium. This condition is produced by an increase in bicarbonate and the development of a metabolic alkalosis. Potassium then leaves the cells to be replaced by sodium, and the potassium is excreted in the urine.

Bicarbonate.—The normal bicarbonate concentration in the plasma is 25-29 mEq/L. Bicarbonate is an end product of metabolism and hence is being continually produced. The concentration of bicarbonate in the extracellular fluid is controlled by the total quantity of base which is available to combine with it. This available base is the difference between the total cations (Na, K, and Mg) in the extracellular fluid and the anions chloride, phosphate, and plasma proteins. This difference is equal to the quantity of carbonic acid which must combine with a base, i.e., Na, to form bicarbonate (NaHCO_3) so that the fluid remains neutral. Bicarbonate ion concentrations depend chiefly upon kidney function, and as long as this is normal, derangements of pH seldom occur.

Normal Fluid Shifts

There is a continuous movement of water and electrolytes, chiefly sodium, between the vascular and the interstitial compartments. This movement is produced by the following:

- 1 The plasma protein concentration, which pulls fluid into the vascular compartment by osmotic action.

2. The intravascular hydrostatic pressure, which forces fluid out of the vascular compartment

3. The shifting electrolyte osmotic pressure of both the interstitial and intravascular areas

For practical purposes the plasma-electrolyte concentration may be taken as being the same as that found in the interstitial fluid, so that a biochemical examination of a sample of blood plasma will reflect the state of the interstitial fluid as a whole (in actual fact, the plasma-electrolyte concentration is slightly higher than that of the interstitial fluid).

Water also moves between the intracellular and extracellular compartments, and this movement is produced by changes in either water intake or output or by abnormal electrolyte losses. If the extracellular sodium level becomes lowered, causing a hypotonicity of this space, water is shifted into the cells in an attempt to bring about normal concentration and isotonicity. On the other hand, if water alone is deficient in the extracellular space, leading to a concentration of sodium, water then shifts out of the cells into the intracellular compartment, tending again to bring about isotonicity.

Disturbances of Acid-Base Balance

Acidosis.—Acidosis is due either to an increase in fixed acid or to a reduction in total available base, either of which will produce a reduction of bicarbonate concentration. This condition may be either respiratory or metabolic in origin.

Metabolic acidosis (acidemia) occurs most frequently in renal insufficiency where there is retention of acid, in uncontrolled diabetes from the production of keto-acids, and from the loss of alkaline secretions containing the sodium ion in severe diarrhea and in intestinal, pancreatic, or biliary fistulas.

Respiratory acidosis is far less common than the metabolic form and occurs where there is an interference with gaseous exchange within the lungs so that carbon dioxide is not eliminated.

Alkalosis.—Alkalosis is a decrease in hydrogen ion concentration and may be due to either metabolic or respiratory derangement.

Metabolic alkalosis (alkalemia) is due to (1) an increased loss of anions (chiefly chloride) in body secretions, such as occurs in the vomiting of pyloric stenosis or accompanies prolonged gastric suction, (2) excess bicarbonate administration, or (3) a potassium deficit.

Respiratory alkalosis occurs because of a decrease in extracellular carbonic acid concentration, as a result of hyperventilation.

Sodium Derangement

The sodium ion is the most important single factor in controlling the distribution of body water because of its high concentration in the extracellular fluid and the slowness of its passage across the cell membrane. Any drop in the concentration of sodium leads to a loss of water; an increase in sodium causes water retention.

Sodium deficiencies are of two types occurring in the following situations. (1) where the total body sodium is normal, but the concentration in the extracellular fluid is low (sodium concentration deficit), and (2) where the total body sodium is reduced (sodium depletion). This is an important consideration as the concentration of sodium in the extracellular fluid does not necessarily reflect the total body sodium; e.g., if the extracellular fluid has been diluted by the addition of large amounts of water, the extracellular concentration is low, while the total body sodium is normal or even increased. Except in edema, sodium concentration deficits rarely occur with sodium depletion. It is this latter syndrome which commonly occurs in the surgical patient.

The symptoms of sodium depletion vary with the magnitude of the loss. In the mild case the early symptoms are anorexia, apathy, lassitude, and weakness. Thirst is usually not present. As more sodium is lost, these symptoms become more marked, nausea and vomiting may occur, and symptoms associated with a decrease in the blood volume manifest themselves (dizziness, fainting, postural hypotension, and severe headache). The skin and mucous membranes show evidence of dehydration. In severe sodium depletion the patient may be stuporous or comatose with a

faint pulse, low blood pressure, atonic muscles, and gross evidence of dehydration

Treatment.—Before any treatment is instituted for the care of a depleted patient a careful evaluation should be made of (1) the case history, with particular reference to duration of illness, amount of vomiting, sweating, fever, and urinary output, (2) a physical examination, particularly noting the state of the mucous membranes, the skin turgor, blood pressure, and the presence or absence of sweating, and (3) laboratory studies of the blood, urine, and body secretions which should include estimation of serum Na, K, Cl, HCO_3 , NPN, hematocrit, and blood volume

Mild sodium depletion is readily treated by the administration of isotonic saline. Severe forms require the use of a hypertonic solution either 3% or 5% NaCl

2. The Intracellular Compartment

Essentially the same ions, although in different concentrations, are present in the intracellular as well as in the extracellular compartment. The dominant cation is potassium, and the dominant anions are phosphate and proteins. There is a continuous but slow movement of fluid and electrolytes between the cells and the extracellular fluid; changes in one compartment cause a compensatory shift of water and electrolytes from the other

Potassium

Ninety-eight per cent of the body potassium is within the cells. Although it is the predominant cation of the cell fluid, it accounts for only two thirds of the available intracellular base, the other one third being magnesium.

The concentration of potassium is 30 times higher in the intracellular compartment than it is in the interstitial fluid. Part of this potassium is in free ionic form, and part is bound to protein. Potassium is an essential part of the cell structure. This fact is evident in starvation, where the increased cellular breakdown which is reflected in nitrogen loss is accompanied by an increased loss of potassium. The ionic potassium renders the intracellular fluid isotonic with the extracellular fluid. Potassium is necessary for adequate cell function, and

any increase or deficiency of this ion is injurious to cell life. The concentration of the intracellular ion is 150 mEq/L.

In addition to the dominant potassium, phosphorus, and magnesium ions, the cells also contain sodium and chloride. The permeability of the cell membrane is under constant metabolic control, and any decrease in the potassium level is countered by a shift of the extracellular sodium into the cells in order to preserve the intracellular electrolyte concentration and provide physiologic isotonicity. If the level of extracellular sodium falls, potassium tends to shift from the cells to the extracellular compartment. However, this shift acts as a very temporary expedient, as the extracellular potassium is rapidly lost in the urine. Potassium is continuously lost via the kidney, which has no power to conserve this ion in times of hypokalemic duress. Only during oliguria or anuria does the urinary potassium appreciably diminish or cease

Potassium Derangement

Excessive extracellular potassium is a highly toxic substance and if increased above physiologic level, will cause myocardial damage. This damage will give typical electrocardiographic changes. If the potassium level rises high enough, the heart will stop in diastole.

Deficiency in potassium also has a profound effect on the organism and occurs in the body according to the following sequence of events:

1. Lack of fluid and electrolyte intake
2. Shift of water and electrolyte from the cells to the extracellular fluid
3. The displaced or shifted potassium is then lost in the urine

Potassium deficiency occurs in the following conditions:

1. Lack of fluid intake
2. Increased abnormal potassium losses such as in vomiting and diarrhea
3. Diabetic acidosis
4. During improper fluid therapy (excessive administration of isotonic saline)
5. In adrenocortical tumors
6. During the administration of adrenocortical hormones

7. A relative deficiency in surgical shock or in thermal burns, as a result of the pooling of noneffective concentrations in, e.g., the area of the burn

8. Certain instances of chronic renal insufficiency

Symptoms.—In *hypopotassemia*, the patient is dull, apathetic, and may be mentally confused. Muscle tone is poor, causing bowel distention and respiratory disturbances. In the extreme case there is a flaccid paralysis of the extremities. The heart sounds are poor, the pulse is slow, and the blood pressure falls.

Hyperpotassemia is rare. Much of the symptom complex is confused with the underlying clinical cause which is usually renal shutdown. It can be caused by overvigorous therapy with parenteral potassium, particularly in the absence of a good urinary output. However, it can occur in patients with normal kidney function if excessive parenteral potassium is administered. Excess oral administration will not cause toxic levels if the kidney function is adequate.

Diagnosis.—The diagnosis of potassium derangement is made by a consideration of the following:

1. The serum electrolyte levels
2. Electrocardiographic changes
3. History of the patient with reference to duration of illness, amount of fluid intake, type of fluid loss, and volume of urine output

Therapy.—In every case of potassium deficiency there is an associated disturbance of the entire body fluid and electrolyte pattern. The administration of potassium must therefore be accompanied by adequate amounts of water, sodium and chloride, optimum caloric intake and, at times, adjustment of the acid-base ratio by the administration of acid or base solutions.

Potassium is best given by mouth, 3 Gm of potassium chloride in 20 ml. of water may be given q 6 h. If intravenous therapy is necessary, 60-80 mEq. may be given daily in the intravenous fluid. Occasionally in cases of extreme deficiency this dose may be increased,

but it is much safer to keep to these levels and be prepared to allow several days for the patient to regain a normal potassium balance. Because of the dangers of hyperpotassemia, an adequate urinary output is a prime essential before intravenous potassium therapy is started.

Dehydration

There are two types of dehydration:

1. *Water and electrolyte depletion (hypotonic dehydration).* This occurs where there is a loss of both body salt and water such as commonly occurs in the severe vomiting of pancreatitis or intestinal obstruction, in the severe diarrhea of ulcerative colitis, or in the case of external intestinal fistula.

The symptoms are due to sodium and fluid deficiency and occur early. There are thirst, weakness, oliguria, and a fall in blood pressure, and there may be peripheral circulatory collapse.

In the early stages of hypotonic dehydration, the fluid and electrolyte loss is chiefly from the extracellular compartment. The loss of salt is relatively greater than the loss of water and causes a hypotonicity of the extracellular fluid. As the dehydration process continues, the intracellular compartment becomes involved with a shift of water and potassium across the cell membrane in an attempt to make up the deficit in the interstitial fluid. Sodium then enters the cells, further decreasing the extracellular level of this ion. The newly shifted potassium is lost in the urine and via the abnormal routes of vomiting and diarrhea. The kidney conserves water, sodium, and chloride, but water continues to be lost via the skin and lungs.

2. *Pure-water depletion (hypertonic dehydration)* There is a loss of water without any loss of electrolytes, leading to hypertonicity of the extracellular fluid. This situation occurs in those conditions where there is a lack of water intake, e.g., in starvation, or in cases where the patient is unable to swallow, such as in esophageal tumors with dysphagia, great weakness, or coma. When all water intake ceases, the body continues to lose water via the kidney, lungs, and skin. The urine output must be

**THE NORMAL FLUID SPACES
IN A 70 Kg MAN**

*Fig 22—A diagrammatic representation of the fluid spaces in a 70 kg man

The volume of the intracellular fluid is shown as 35 L. and that of the extracellular as 14 L. The concept of continuous shift of Na and K between the intracellular and extracellular compartments is indicated by the two directional fine arrows and that of the continuous K loss by the normal kidney with a normal urine output, by a single fine arrow. The Mg ion behaves in a similar fashion to the K ion. There is only a small loss of Na and Cl in the urine, due to the kidney mechanisms, which preserve the normal body concentration of these ions. The hematocrit is normal and is indicated by RBC 45%.

at least 500 ml./24 hours in order to excrete nitrogenous waste products. The skin and lungs usually account for an additional loss of 1,000 ml. This total of 1,500 ml. is called the obligatory water loss. It can be seen that this continued loss of 1,500 ml/24 hours, without adequate replacement, will rapidly lead to dehydration. As there is little electrolyte

*Figs 22-27 depict the direction of fluid and electrolyte shifts which occur during different degrees and forms of dehydration. The magnitude of these shifts is also roughly indicated.

**EARLY RAPID OR HYPOTONIC
DEHYDRATION**

Fig 23—Early rapid or hypotonic dehydration

This condition results where there is loss of both water and electrolytes, e.g., in severe vomiting or intestinal obstruction. The magnitude of the electrolyte loss is relatively greater than the fluid loss. The dehydration is initially limited to the extracellular fluid, although there is a beginning instability of the intracellular compartment. There is a reduced urine output and a slightly increased K and Mg loss. There is no urinary Na or Cl loss, as the kidney is acting to conserve these ions. The hematocrit is significantly elevated.

loss, and that chiefly potassium, the extracellular fluid becomes hypertonic. The cells put out water in an attempt to maintain intracellular and extracellular isotonicity. With this water shift, cellular potassium also moves across the cell barrier to be, in time, lost in the urine. As the lack of fluid intake is usually accompanied by a lack of caloric intake, cellular breakdown occurs, contributing to the potassium loss.

In contradistinction to the hypotonic dehydration, the water deficit is manifest equally

LATE RAPID OR HYPOTONIC DEHYDRATION

Fig 24—Late rapid or hypotonic dehydration

This state occurs in untreated severe cases of fluid and electrolyte loss. There is now a marked depletion of water from both compartments. The K loss in the urine is excessive, although the urine output is markedly reduced. There is also a loss of Mg. There is no urinary Na or Cl loss. The degree of hemoconcentration, as evidenced by the hematocrit, is high.

throughout the intracellular and extracellular compartments.

Signs and symptoms are severe thirst, weakness, dry, loose and inelastic skin, and oliguria, and there is no history of abnormal fluid and electrolyte losses.

Parenteral Fluid in Surgical Patients

The parenteral fluid requirements of surgical patients are estimated by a study of the three factors which bring about dehydration.

1. The deficit which has already resulted prior to the institution of therapy. This is the sum of the abnormal losses and the continued obligatory losses which have continued since the onset of the illness.

SLOW OR HYPERTONIC DEHYDRATION

Fig 25—Slow or hypertonic dehydration

This is a condition that results from water starvation without any extraordinary loss of electrolytes. The dehydration is manifested equally in both the intracellular and extracellular compartments. There is increased K and Mg loss in the urine as a result of the intracellular fluid shift. There is an increased shift of Na into the cells to compensate for the ionic K loss. There is a slight loss of Na and Cl in the urine, as the renal conservation mechanism of these ions has not yet come into effect. The urine output is reduced. The hematocrit tends to be elevated.

Treatment consists of rehydration by isotonic carbohydrate solutions. K may be necessary in late cases.

2. The future daily normal fluid requirements of the patient. A basic quantity of 1,500 ml. for obligatory loss and 1,000-1,500 ml. for urinary output should be allowed.

3. The correction of continued abnormal loss from vomiting, continuous gastric suction, etc.

In all surgical patients who come to operation, it is convenient to divide the fluid requirements of each patient into three time phases: the preoperative phase, the operative phase, and the postoperative phase.

LATE RAPID DEHYDRATION TREATED WITH NaCl ALONE

Fig. 26.—Late rapid dehydration treated with NaCl alone

The NaCl solution tends to overhydrate and expand the extracellular fluid compartment and to some extent the intracellular compartment as well. The excess of the Na ion tends to increase Na shift into the cells and to increase K and Mg loss in the urine. There is an increased urinary loss of Na and Cl as a result of the kidney's efforts to reduce the overabundance of these two electrolytes. The urine output lags behind the fluid intake. The hematocrit is reduced because of the retained fluid. Clinical edema may be present.

The Preoperative Phase.—The preoperative phase may not present any problem in the case of a healthy individual whose fluid needs are met by a regular oral intake of food and water. However, the problem may be complicated by a prolonged period of wasting illness, vomiting, shock, or hemorrhage, and careful parenteral therapy will then be necessary.

LATE RAPID DEHYDRATION TREATED WITH BALANCED ELECTROLYTES

Fig. 27.—Late rapid dehydration treated with balanced electrolytes

The potassium deficit is met by KCl, the Mg deficit by MgSO₄, the Na deficit by NaCl and NaHCO₃, and the Cl deficit by the KCl and NaCl. Excess Cl administration is avoided by the use of NaHCO₃, as the HCO₃ is eventually excreted by the lungs as CO₂. The water deficit in both compartments is corrected. The urine output and hematocrit are normal.

The history and physical examination afford the basis for estimating the amount and type of the fluid and electrolyte deficiency. The frequency, severity, and type of vomiting must be recorded. The duration of the illness enables one to estimate the amount of obligatory water loss. A knowledge of the urinary output is all-important. The physical examination shows the presence of fluid which is not available to the body, e.g., in edema, gastrointestinal ileus, etc. The degree of intestinal motility is an important point. Lack of intestinal motility usually means that there

is a large noneffective pool of water within the lumen of the bowel. Examination of the facial expression, tissue turgor, and blood pressure should always be made. The amount of thirst, the presence of sweat, and the condition of the peripheral circulation also give evidence of the degree of dehydration.

Laboratory Examinations.—There are several laboratory examinations which should be carried out in each case of dehydration. It should be remembered, however, that these laboratory tests do not afford a diagnosis of the type of dehydration. This must be made on clinical grounds. The following is a list of the determinations which are commonly used:

1. Red blood count, hemoglobin, and hematocrit
2. Urinalysis
3. Blood nonprotein nitrogen
4. Serum electrolyte estimations of sodium, potassium, and chloride
5. Carbon dioxide content of the blood
6. Blood volume estimations, using T-1824, Evans' blue dye, or radioactive tracer substances such as phosphorus, iodine, or iron
7. Serial determinations of the body weight

The Operative Phase.—Fluid and electrolyte requirements during the operation are mainly supportive. Large amounts need not be given except in the case of the patient with a high fever, or during excessive sweating as may occur on a very hot day. The most important fluid given in the operating room is the replacement blood transfusion. The time to administer blood is during the time that the actual loss is taking place. Thus the intravascular shift of the interstitial fluid in an attempt to maintain plasma volume is avoided.

The Postoperative Phase.—The fluid requirements should be planned to maintain the urinary output at between 1,000 and 1,500 ml/24 hours. This amount may have to be increased if there is evidence of poor urinary function. Due allowance must be made for the obligatory losses of the skin and lungs, and for the abnormal losses which may occur chiefly via continuous nasogastric suction, gastrointestinal fistula, ileostomy, etc.

Sedation

It is essential that every surgical patient have a good night's sleep before the operation. Rest must not be left to chance but should be assured by the use of a suitable soporific drug, such as one of the short-acting barbiturates. The sedative is preferably given by mouth, but subcutaneous or intravenous injection may at times be necessary.

Care of the Gastrointestinal Tract

No useful purpose is gained by the routine use of enemas or purgation. The use of these drastic measures should be limited to those patients in whom an empty bowel is necessary for the successful completion of an operative procedure, and to those patients in whom a period of postoperative immobilization is anticipated. In these latter patients it is usually sufficient to administer a simple enema on the night before the operation. However, in the case of patients who are scheduled for operative procedures on the colon or rectum, cleansing enemas should be given on the night prior to operation and repeated early on the morning of operation. Care should be taken that the enema be completely expelled, an effect best accomplished by allowing the patient to walk about for a time following the administration of the enema. Breakfast should be withheld for all patients who anticipate a morning operation which requires general anesthesia. However, for patients listed for afternoon operations, an easily assimilated breakfast should be given early in the morning. Patients who require minor surgical procedures under local anesthesia are best advised to eat their normal breakfast or other meal.

Skin Preparation

A wide area of skin about the proposed incision should be carefully prepared. All hair should be removed by meticulous shaving, and the area should be washed with soap and water. Occasionally it is advisable to paint the prepared area with an antiseptic solution and cover it with a sterile towel.

Preoperative Medication (See Chapter 8, Anesthesia.)

PREOPERATIVE AND POSTOPERATIVE CARE

FIG. 29 Diagram of areas of skin preparation

POSTOPERATIVE MANAGEMENT

The Endocrine and Metabolic Responses to Injury

Every surgical operation is followed by a period in which the patient needs special care in order to minimize his discomfort and to prevent the complications. There is a systemic reaction to bodily injury characterized by various changes principally in the adrenal cortex, posterior pituitary, and the metabolism of protein and electrolytes. This is a normal response occurring in the healthy individual which presumably is due to a compensatory reaction to a state of stress.

Endocrine.—

Adrenal Cortex.—Following operation or injury, the adrenal cortex secretes large quantities of hormones which cause metabolic changes in the patient subjected to this stress. These changes are nonspecific in character and generally are related to the magnitude of the injury. These adrenocortical changes may be measured by the eosinophil response and by the 17-ketosteroid and aldosterone levels. The normal eosinophil count in the adult ranges, on the average, from 150 to 500. Following a surgical procedure of medium severity, the count rapidly falls to about 10% of normal, if the injury is of major severity the count may fall to zero. After moderate trauma the eosinophil count will return to normal within 24-48 hours, while after major trauma the count remains low for 2-5 days. If the injury is continued as in major burns, the eosinophil count remains low for a much longer period, i.e., up to 2 weeks.

As in the case of the eosinophils, the urinary hydroxycorticoids are affected by the degree of trauma. A moderate degree of injury produces an increase from the normal excretory level of 5-10 mg/24 hours, up to 20-25 mg/24 hours. Major injuries produce increases up to 50 mg/24 hours. The increased excretion lasts about a day after moderate injury, 3-5 days after major injury, and up to 2 weeks following a severe burn. The blood steroids follow a similar pattern after trauma.

Following trauma the urinary level of aldosterone (normal 4-8 μ g.) rises rapidly for 24 hours and then falls to normal. This rise

appears to be due to either an increased output of ACTH or psychic stress. The sodium and potassium response which accompanies this phenomenon cannot be ascribed to the rise in aldosterone but is due to the increase in gluco-corticoids.

Posterior Pituitary.—Following surgery there occurs a change in water metabolism characterized by a decreased water excretion and a tendency of the body to conserve water. While not proved to be due to the antidiuretic hormone liberated by the posterior pituitary, the evidence strongly suggests that this is the case.

Thyroid.—There is an increased oxygen requirement following injury. This is readily measured by serial B.M.R. determinations which show increases up to 50-60 following injury and a return to normal in 5-6 days.

Metabolic.—Following operation or injury there is an increase in nitrogen loss in the urine. In surgery of moderate degree there is a slight increase in the nitrogen loss, which is in part due to starvation, in part due to stress. Following major surgery or trauma, the nitrogen loss is greatly increased, up to 15 Gm/day, and even as high as 25 Gm/day in severe crushing injuries and burns. Negative nitrogen balances may continue for a period of 1-2 weeks, even when the nitrogen intake is normal. During most of this catabolic phase, nitrogen appears in the urine as urea and occurs chiefly as the result of breakdown of skeletal muscle plus the general effect of starvation in the early posttraumatic phase. In addition to the protein derangements which result from injury, similar upsets occur in the metabolism of carbohydrate, fat, and vitamins.

Electrolytes.—Following injury potassium is lost as a result of starvation and the catabolic effect of injury. After major trauma, the urinary potassium loss in the first 24 hours ranges from 50-70 mEq. This amount decreases to 20-30 mEq per day within 3-4 days. This potassium loss is greater than can be accounted for by starvation. In starvation the potassium-nitrogen ratio is about 3 mEq/Gm., but following injury the ratio is about 5-10 mEq/Gm.

The excretion of sodium and chloride is contradistinct to potassium is reduced fol-

lowing injury. This conservation of extracellular ions is greater than can be accounted for by starvation alone. The serum sodium levels are reduced in spite of the retention of sodium, a reduction probably due to a retention of water and a shift of sodium into the intracellular compartment.

If the body is to survive following injury, these metabolic changes must take place. Whether such changes are caused by or accompany the alterations in adrenal steroid metabolism is uncertain, but they do occur together.

Patients who have had major surgical procedures require continuous and expert observation during the initial postoperative phase. This management is ideally carried out in a well-equipped recovery ward which is staffed by personnel, professional and nursing, specially trained in the use of resuscitation measures and in the accurate recording of data. Patients should remain in such a ward until the acute postoperative phase is over.

Pain

Pain in the operative area is often accentuated by the anxiety of the patient. The most effective method to relieve pain is the hypodermic injection of morphine sulfate, gr $\frac{1}{8}$ - $\frac{1}{4}$ (7.5-15 mg.), repeated at 4-hour intervals when necessary. This drug should be used with caution, especially in the older age groups because of its depressant effect on the respiratory center. Care should be taken that doses of morphine larger than absolutely necessary are not used; 10 mg. of morphine sulfate/70 kg. of body weight will, under usual circumstances, afford adequate pain relief. Doses in excess of this amount lead to a great increase in uncomfortable side effects, e.g., nausea, vomiting, and respiratory depression, and add as a rule little to the degree of pain relief. Of course, if severe pain occurs, larger doses are indicated. Demerol, 100-150 mg., may be substituted for morphine. This drug produces less respiratory depression and does not cause the unpleasant side effects of nausea and vomiting, which so frequently occur following the administration of morphine. It should only be necessary to continue these drugs for the first 24-48 hours postoperatively. If discomfort per-

sists, milder analgesics such as codeine and acetylsalicylic acid may be given. Apprehension is best relieved by reassurance, supplemented in some cases by suitable barbiturates. Chlorpromazine is a useful adjunct, both as an analgesic and a sedative. The combination of chlorpromazine with Levo-Dromoran is particularly useful in the pain of advanced malignancy. The use of intravenous ethyl alcohol 5% and intravenous procaine 1% is frequently helpful in controlling pain on a short-term basis. Local nerve blocks occasionally are helpful.

Fluids

In the immediate postoperative period, the fluid requirements of the surgical patient are increased due to operative blood loss, increased sweating, gastric or other intestinal drainage, and vomiting. In the absence of nausea and vomiting, the oral administration of water may be started in small amounts as soon as the patient has recovered from the anesthetic and may be increased as rapidly as his tolerance permits. If the patient cannot take his fluid requirements by mouth, parenteral fluids should be given in such an amount as to ensure a urinary output of 1,000-1,500 ml. daily. It is extremely essential that careful records be kept of the fluid intake and output of each patient, in order that the fluid balance may be regulated. (See Chart 1.)

Diet

The details of diet vary widely with the various operative procedures. The aim should be to return the patient to a full and adequate oral intake as soon as possible. Following minor surgical procedures, and in the uncomplicated case, the patient can take enough food to maintain his nutrition, but after major surgical procedures it is frequently necessary to supplement the oral intake by parenteral means.

The important points of any dietary program are as follows:

1. To resume a normal oral intake at the earliest moment.
2. To supply a maximum amount of nourishment in a volume which can be readily taken by the patient. This nourishment must be presented in a palatable form.

3 To supply nourishment, by special dietary means, to patients who have undergone operations which prevent a sufficient oral intake, e.g., to postgastrectomy patients for whom supplementary intravenous amino acids may be used; to postjejunostomy and gastrostomy patients for whom specially prepared liquid feedings are required

The following basic formula affords a balanced diet for patients following a gastrostomy or a jejunostomy. This concentrated formula must be reached after a 14-day period of graduated feeding increases

Gastrostomy and Jejunostomy Feeding

Whole boiled milk	1,500 ml
Water	500 ml.
Dextrin-Maltose (No 1 or 2)	100 Gm
Strained liver	4 (3½ oz.) tins
Fat emulsion (Lipomul)	100 ml.
Protein powder (Gevral)	60 Gm.

Analysis

Protein	135 Gm.
Fat	115 Gm.
Carbohydrate	190 Gm
Calories	2,335
Volume	2,650 ml

Vitamins	adequate
Minerals	adequate
Sodium	47.24 mEq./L.
Potassium	50.52 mEq./L.
Chlorine	9.05 mEq./L.
Phosphorus	57.4 mEq./L.

The feedings are increased according to the following plan:

1st day	Whole boiled milk	500 ml.
	Water	500 ml.
3rd day	Whole boiled milk	1,000 ml.
	Water	500 ml.
5th day	Whole boiled milk	1,500 ml.
	Water	500 ml.
	Dextrin-Maltose	
	(No 1 or 2)	50 Gm.
7th day	Whole boiled milk	1,500 ml.
	Water	500 ml.
	Dextrin-Maltose	
	(No 1 or 2)	100 Gm.
	Strained liver	1 (3½ oz.) tin
9th day	Whole boiled milk	1,500 ml.
	Water	500 ml.
	Dextrin-Maltose	
	(No. 1 or 2)	100 Gm.
	Strained liver	2 (3½ oz.) tins
11th day	Whole boiled milk	1,500 ml.
	Water	500 ml.
	Dextrin-Maltose	
	(No. 1 or 2)	100 Gm.
	Strained liver	3 (3½ oz.) tins

PREOPERATIVE AND POSTOPERATIVE CARE

13th day	Whole boiled milk	1,500 ml
	Water	500 ml
	Dextro-Maltose	100 Gm
	(No 1 or 2)	4 (3½ oz) tins
	Strained liver	100 ml
	Lipomul	

Most patients are benefited by dietary supplements in the form of high protein drinks which should be given in the preoperative and postoperative periods. A useful and palatable formula is as follows:

High Protein Eggnog

Recipe		100 ml
Cream 15%		1,300 ml
Milk		5 only
Eggs		20 Gm
Sugar		75 Gm
Skim milk powder		30 ml
Vanilla		1,700 ml
Volume		

Analysis per liter

Protein	60 Gm
Fat	55 Gm
Carbohydrate	75 Gm
Calories	1,036
Sodium	360 mEq/L
Potassium	54.7 mEq/L
Chlorine	42.7 mEq/L
Phosphorus	418 mEq/L

Oral feedings are not to be attempted until the motility of the gastrointestinal tract has returned to normal. The resumption of normal motility can be ascertained by abdominal palpation, abdominal auscultation, and by the evidence of the passage of flatus per rectum. Stomach emptying can be gauged by the aspiration, at timed intervals, of measured amounts of fluid which have previously been introduced into the stomach via an indwelling nasogastric tube.

Care of the Lower Gastrointestinal Tract

The diet during the first few postoperative days ensures little residue. There is, therefore, no necessity for an evacuation before the third postoperative day. During this time, a rectal tube may be used to relieve flatus. If the bowels do not move by the third or fourth postoperative day, a small enema may be given. If enemas are ineffectual, rectal examination should always be done to exclude impaction of feces in the rectum. Fecal im-

paction can also produce symptoms of diarrhea and tenesmus.

Should fecal impaction occur, the feces should be softened by oil retention enemas, and if no evacuation occurs, manual removal becomes necessary.

Ambulation

The patient should be turned on alternate sides every hour and should be encouraged to breathe deeply and to cough. His respiratory excursions may be increased by the administration of carbon dioxide (5%) and oxygen. The patient should be allowed out of bed as soon as possible, but no hard and fast time schedule should be followed; rather each patient should be judged individually. His general condition, the nature and extent of the operation, and the presence or absence of complications must be considered. It is important to insist on early active movement. The practice of lifting a patient into a chair where he remains immobile until lifted back into bed does not constitute early ambulation. Many patients, including those who have had abdominal operations, may be allowed up in 24 hours, allow to walk to the bathroom after 48 hours, and within 4-5 days may be permitted to be up and about most of the time.

Such a program adds immeasurably to the well-being of the patient and results in fewer pulmonary complications, briefer convalescence, and easier nursing care. The incidence of wound disruption and postoperative hernia has not been increased. However, phlebotrombosis and subsequent pulmonary embolism may still occasionally occur in patients who have followed this regime.

Care of the Wound

In the so-called clean case, in the absence of fever, undue pain, or discharge in the operative area, the dressings need not be disturbed until the time for removal of suture. Heavy dressings should be avoided. Repeat inspections of the wound are unnecessary, in addition to the patient's discomfort, and may predispose to infection.

All changes of dressing must be done using the most scrupulous aseptic technique. In order to avoid infecting himself, or the trans-

PREOPERATIVE AND POSTOPERATIVE CARE

in and feel the ribs expanding against the hands. On expiration, a gentle pressure should be given with the hands at the end of the movement.

The patient is taught localized breathing exercises, that is, diaphragmatic and lower lateral costal breathing. It is most important to teach these exercises for at least two days prior to operation, in order to thoroughly ventilate the lungs and also to ensure that the patient fully understands what he will have to do postoperatively. If the patient does not know this before the operation, it is often very difficult to teach him afterward when he is in a state of shock and suffering pain. Most patients require treatment for about three days after the operation—they are treated twice a day if necessary.

Pulmonary Embolism.—Pulmonary embolism usually follows thrombosis of the veins of the legs and pelvis. In contrast to pneumonia and atelectasis, pulmonary embolism rarely occurs before the end of the first week after operation. Fatal embolism is often preceded by smaller, nonfatal infarcts.

The clinical manifestations depend upon the size of the embolus and its location. If a main pulmonary artery is occluded, the symptoms are those of acute respiratory distress with circulatory collapse. If a smaller branch is blocked, the patient has pain in the affected side of the chest, dyspnea, cyanosis, fever, and hemoptysis in the early stages frequently fail to demonstrate the lesion.

Treatment.—Careful daily examination of the legs for signs of thrombosis should always be done. At the first sign of involvement of the veins, anticoagulant (Marcumar) therapy should be instituted. Measures such as papaverine occurs, antishock measures such as papaverine should be given. Oxygen and anticoagulant therapy must be continued. If recurrent emboli occur, ligation of the inferior vena cava should be carried out.

Fat Embolism.—Fat embolism usually follows severe trauma and fractures and is due to the presence of fat globules in the circulating blood. The etiology is obscure and the condition may be due to either a disturbance in general fat metabolism or the liberation of fat globules at the site of trauma.

The symptoms are predominantly cerebral or pulmonary. The patient is restless, confused, and possibly comatose and may develop dyspnea, cyanosis, and signs of pneumonitis. Patechiae are often present over the upper thorax and neck. The diagnosis is established by the presence of fat in the sputum or urine. Treatment is directed toward the relief of shock and pulmonary complications.

Gastrointestinal Complications

Nausea and Vomiting.—Nausea and vomiting are common in any patient who has had a general anesthetic and are aggravated by excessive intake of fluids or food in the immediate postoperative period. Many patients are sensitive to morphine, which may prolong and increase vomiting. If vomiting is prolonged, it becomes potentially dangerous because of the resulting dehydration and chloride loss. In such cases, continuous gastric suction should be instituted and parenteral fluids given.

The use of certain proprietary drugs, Dramamine, Gravol, or Stemetil (prochlorperazine), by oral, intravenous, or rectal routes is useful in the so-called idiopathic nausea of the postoperative period. On no account should these drugs be used to alleviate the nausea and vomiting of postoperative ileus or some other similar pathologic state.

Abdominal Distention.—Following every abdominal operation a certain degree of temporary paresis of the intestines occurs, but the bowel musculature quickly regains its tone. Accumulation of gas within the intestinal lumen and the ineffectual efforts to expel it result in the so-called gas pains. The atony persists in some cases, due to prolonged or rough handling of the bowel, retroperitoneal hemorrhage, peritonitis, or operations on the retroperitoneal tissues. If this complication is not recognized early and treated promptly, increasing distention of the bowel will result. The amount of intestinal gas is derived from swallowed air, with only a small proportion coming from fermentation of food and interchange of gases with the blood stream. It is much easier to prevent than to treat ileus. In the early stage, a rectal tube may permit the passage of flatus with marked relief. Early prompt use of gastric intubation with continuous suction will

prevent distention in the majority of cases. Intestinal intubation with the Miller-Abbott, Harris, or Cantor tube will overcome ileus if the tube can be passed into the small bowel. In our experience, a single wide lumen tube fitted with a mercury bag, such as is provided in the Cantor tube, is the most satisfactory type. (See Fig. 29.) Drugs have a limited field in the treatment of intestinal ileus. Morphine enhances both the tone and the peristaltic action of the intestine, especially of the small bowel. (See Chapter 24, Intestinal Obstruction.) As a rule, no drugs appear to be of value until peristalsis is resumed.

dilated stomach. Continuous suction on the stomach tube should be maintained until the gastric tone is restored. One questions whether this is a true disease entity or a manifestation of paralytic ileus.

Hiccough.—Postoperative hiccoughs may occur following operations on the abdominal viscera, the genitourinary tract, the diaphragm, or the central nervous system. It is thought to be a reflex phenomenon due to stimulation of the afferent nerve terminals in the diaphragm. It is usually transitory and responds to symptomatic treatment, but it may be prolonged and very refractory to therapy.

Fig. 29.—Types of nasogastric tubes in common use

Acute Dilatation of the Stomach.—This condition may follow any operation and is regularly associated with paralytic ileus. There is loss of gastric tone, and large quantities of gas and fluid accumulate in the stomach. The enlarged, dilated stomach can be palpated, and large quantities of fluid are vomited. The treatment depends upon early diagnosis and the immediate removal of the contents of the

stomach. Inhalation of carbon dioxide (5-10% in oxygen) is often effective. As hiccough frequently accompanies an ileus or stenosis in the intestinal tract, gastric suction may bring relief. Chlorpromazine given parenterally will usually relieve hiccough of idiopathic origin. In the intractable case it is occasionally necessary to interrupt the phrenic nerve, either by local anesthesia or operative procedures. If

PREOPERATIVE AND POSTOPERATIVE CARE

this is done the patient first should be fluoroscoped in order to determine which side of the diaphragm is producing the hiccough.

Parotitis.—This condition is an uncommon postoperative complication. The invading organism, usually a staphylococcus, enters via the parotid duct. A dirty mouth in a dehydrated patient is undoubtedly a predisposing factor, and the condition generally occurs in debilitated individuals.

Pain, swelling, and tenderness in the parotid region accompanied by pyrexia appear within a few days of operation, and pus can often be expressed from the opening of the parotid duct.

The treatment of oral sepsis and the prevention of dehydration will prevent the occurrence of parotitis. Once the infection is established, antibiotic therapy is of great value, combined at times with small doses of x-ray to the parotid region.

Urinary Complications

Urinary Retention.—Inability to void is common in the immediate postoperative period and is, as a rule, transitory. Many patients experience difficulty in voiding while recumbent, getting the patient out of bed frequently enables him to empty his bladder. Parasympathetic drugs are sometimes useful. If such measures fail, catheterization is necessary. Overdistention of the bladder predisposes to infection, and catheterization should be done before overdistention occurs. Great care must be taken to avoid introducing bacteria into the bladder during this procedure. If retention persists, an indwelling catheter may be introduced, and tidal drainage is occasionally indicated.

Oliguria.—Some degree of oliguria always occurs in the first postoperative day. This is due to a variety of factors: the lack of fluid intake, excessive sweating, fever, vomiting, hyperentilation, the specific effect of the adrenal cortex on the kidney, and the use of continuous gastrointestinal suction. Oliguria is arbitrarily assumed to be present if the urinary output is less than 500 ml./24 hours. This amount is the minimum urinary output required for the excretion of nitrogenous waste products if the renal function is normal. This initial period of oliguria is not alarming, par-

ticularly if the urinary specific gravity is high. Persistence of oliguria means either an inadequate fluid therapy or renal damage. If the specific gravity is persistently low or if the patient has a marked positive fluid balance or if he develops edema, impaired renal function should be immediately suspected.

Anuria.—Anuria may complicate surgical operations, especially when accompanied by hypotension and shock. Dehydration and previous kidney disease are predisposing factors. Following severe burns, incompatible blood transfusions, etc., lesions of the lower nephron nephrosis type occur, and the functional derangement may lead to complete anuria. In many cases the kidneys begin to function spontaneously after a few days. Great care must be taken that the patients are not overloaded with fluids during this period. (See Chapter 31, Genitourinary System.)

Wound Complications

Infection.—Infection should not occur in a clean case. If it does, a careful review of the operation and dressing techniques must be made. Infection is usually restricted to a small part of the wound, but a generalized wound infection and spreading cellulitis may occur. Clinically the patient runs a normal course for several days and then develops fever and pain at the operative site. Examination of the wound may show swelling and redness, but often a localized point of tenderness is the only indication of underlying infection. The wound should be reopened, the pus evacuated, and antibiotics administered.

Hematoma.—Hematomas may occur in any operative wound. The incidence is inversely proportional to the surgeon's care in effecting hemostasis. Small hematomas will be absorbed spontaneously but predispose to infection. Large hematomas should be evacuated under anesthesia and the wound resutured, as retained blood clot markedly delays wound healing.

Disruption of the Wound.—This condition occurs more commonly in the aged and obese, in patients with debilitating disease, such as cancer, and in those who experience vomiting, distention, or cough in the postoperative period. Incomplete wound disruption is the

basis for almost all incisional hernias. It commonly occurs about a week after operation.

Wound disruption should be suspected if there is any constant outpouring of straw-colored or blood-stained fluid. Frequently the patient experiences a sensation of something breaking or, as he says, "letting go," particularly during a paroxysm of coughing. A small piece of omentum appearing in the wound should not be confused with subcutaneous fat.

To minimize the incidence of wound disruption, the patient's nutritional status should be satisfactory before operation; the incision should be closed carefully and without tension on the suture line; and wounds of debilitated patients should be closed with through-and-through nonabsorbable sutures.

Treatment.—The wound should be immediately resutured with through-and-through nonabsorbable sutures, unless the patient's condition is so critical that any operation is contraindicated, in which event adhesive strapping may serve as a temporary measure.

Headache

Headache is a common complaint following spinal anesthesia. It is frontotemporal and/or suboccipital in location. The pain is usually absent when the patient is lying flat in bed and develops when the patient sits up or stands. The pain is aggravated by sneezing, coughing, and bodily exertion.

The cause is somewhat equivocal, but it is most likely due to a slow leakage of spinal fluid through the puncture site in the fibrous, inelastic, and slowly healing dura. The loss of more than 10% of the spinal fluid volume causes intracranial changes, such as dilatation of the intracranial vessels, chiefly the veins, and some increase in the brain volume. Occasionally the headache is associated with a low-grade aseptic meningitis.

Headache may also be caused by extracranial muscle spasm, due to trauma from the lumbar puncture, posture on the operating table, and undue postoperative immobilization.

The treatment is unsatisfactory. The pain will normally pass off within a week. Great relief is afforded by strict recumbency. Analgesics should be used. Occasionally intracranial vasoconstrictor agents, such as ergotamine in

combination with caffeine, may be given in the proprietary tablet Cafergot (100 mg. caffeine nitrate and 1 mg. of ergotamine), two tablets every 30 minutes, for 4-6 doses. Hydration of the patient will also prove useful.

Skeletal muscle spasm is helped by local physiotherapy and sedatives.

PATIENTS PRESENTING SPECIAL PROBLEMS

Infants and Children

Infants and children are particularly susceptible to disturbances in metabolism as a result of operative trauma. They require a much greater caloric, water, and salt intake per kilogram of body weight than do adults.

The effects of dehydration are more profound and occur more rapidly in infants and young children. The average daily fluid intake of infants and young children is approximately 700 ml/24 hours, and the urinary output is of the same order. The extracellular compartment of these patients is about $\frac{1}{10}$ that of an adult, i.e., $1\frac{1}{2}$ L. Therefore, any decrease in the fluid intake will have a rapid and profound effect on the small amount of body fluid. Likewise, any increased loss of fluid, either through vomiting or excessive sweating, will soon deplete the extracellular compartment and lead to a severe dehydration. The normal infant requires about 150 ml of fluid/kg of body weight daily. In the surgical patient this amount should be given by a slow, continuous intravenous drip, the rate not to exceed 30-60 ml/hour. The blood volume of infants is extremely small. Therefore, any operative procedure should be carried out with a replacement blood transfusion. This should not exceed 25 ml/kg. at any one time, unless there is an inordinate degree of blood loss.

The Elderly Patient

The elderly patient reacts less favorably to trauma than does a younger person. Advanced age is frequently associated with nutritional deficiencies and cardiovascular, renal, or respiratory disease, any of which will add to the operative risk. However, with careful preoperative and postoperative care, proper choice of anesthetic agents, and meticulous surgical

PREOPERATIVE AND POSTOPERATIVE CARE

technique, the average elderly patient will come through even an extensive surgical procedure without difficulty.

The postoperative phase of treatment is most important, for patients even with outwardly good cardiovascular or renal function may develop a breakdown of these systems, and special precautions must be taken to forestall any such event. An adequate urinary output is most important to ensure that the nitrogenous waste products are excreted, because the renal concentrating power may be reduced.

To help guard against cardiac complications, salt intake should be restricted for several days prior to any major surgical procedure. Intravenous feeding must be done with great care to avoid overloading the circulation with ill-chosen or rapidly administered solutions.

Respiratory complications frequently develop in the elderly patient from concomitant chronic respiratory disease or from inability to cough up retained bronchial secretions. Assiduous nursing care and prophylactic chemotherapy will prevent most complications of this type.

It should be realized that the chronologic age of a patient is a poor guide to his physiologic state, and the planning of therapy should be based on his physiologic age. Persistent vomiting in an elderly patient does not rapidly deplete the patient's reserve of water and salt because his gastrointestinal secretions are smaller in volume and have a lower electrolyte content. However, the blood volume of elderly patients, particularly if their nutrition has been poor, is frequently low, and small losses of fluid may lead to peripheral collapse. This small blood volume, the so-called state of chronic shock, should be treated with judicious preoperative whole blood transfusions, and extremely carefully judged replacement blood transfusion during any operative procedure.

The Patient With Cardiovascular Disease

The patient with cardiovascular disease, whether young or old, who undergoes a surgical procedure does so with added risk. However, except in the presence of cardiac decompensation, or following a recent cardiac accident, or in severe congenital heart disease, this risk should not be inordinately great.

Patients with chronic rheumatic heart disease, angina pectoris, and hypertension without stand extensive surgical procedures without difficulty, if certain precautions are observed. The preoperative sedation should be sufficient to allay apprehension, yet not enough to cause marked cerebral or respiratory depression. Anesthetic agents must be administered with extreme care to avoid struggling during the stage of excitement, and anoxemia and hypotension must be prevented at all times. Intravenous fluids must be given very carefully to avoid overloading the right side of the heart, with the dangerous consequence of pulmonary edema. Nonelectrolyte crystalline solutions are usually well tolerated, but sodium chloride is best avoided because of its tendency to increase the blood volume. Whole blood and blood plasma should only be given to replace their loss.

The most important practical point in assessing the operative risk in cardiac patients is the degree of exercise tolerance and the presence or absence of cardiac decompensation. The use of digitalis and quinidine is indicated, unless cardiac irregularity or failure develops during the postoperative period.

The Patient With Renal Disease

The patient with chronic renal insufficiency constitutes a great problem to the surgeon. The impaired powers of concentration and selective absorption of the renal tubules require that special attention be paid to fluid and electrolyte requirements, to ensure adequate excretion of waste products and a satisfactory electrolyte balance. The greater the degree of impairment of function, the greater the urine volume required. Renal failure or shutdown, which can occur with great suddenness in cases with impaired renal function, usually occurs after a period of hypotension or dehydration, and these events should be avoided at all costs. Acute renal disease, such as pyelitis and nephritis, should be treated before any but emergency surgical procedures are carried out.

The routine unalysis is the best guide to the detection of renal disease. The finding of albumin, casts, red blood cells, or a low fixed specific gravity is sufficient to warrant a complete urinary tract investigation and should

include biochemical studies, e.g., NPN and creatinine, urea clearance test, a test of the excretory power of the kidney by the phenol-sulfonphthalein reaction, and a test of the urinary concentration power of the kidney (Mosenthal). Special roentgenologic tests and instrumental examination of the kidney and lower urinary tract should also be carried out.

The Patient With Respiratory Disease

Chronic respiratory disease augments the risk by leading to an increased incidence of postoperative pulmonary complications. With the impaired respiratory excursion and the deficient aeration of the lungs, most anesthetic agents are poorly tolerated. Careful attention to oxygen supply and a free airway is most essential during operations on patients with chronic respiratory disease. Postural drainage with parenteral and aerosol chemotherapy should be used during the preoperative and postoperative phases.

Acute respiratory infections necessitate the postponing of elective surgical procedures. If an emergency arises, inhalation and parenteral chemotherapy should be employed. In any case of pulmonary disease, particular effort must be directed to the clearing of tracheal and bronchial secretions by coughing, tracheal aspiration, early movement, and ambulation.

The Obese Patient

Obesity, particularly in the older patient, increases the operative risk, first, because of its frequent association with metabolic disturbances or with organic, cardiac, or respiratory lesions, and, second, because of the difficulties encountered in carrying out surgical procedures, especially those within the abdomen.

Weight reduction should be attempted prior to elective surgical procedures. However, in the event of emergency, the added risk must be accepted.

Diabetes in the Surgical Patient

Surgery in the Presence of Diabetes.—The surgical management of the diabetic patient necessitates close cooperation between physician and surgeon. If the hypergly-

cemia is not controlled, the incidence and severity of infections will be increased, delayed wound healing may occur, and glycosuria, acidosis, and coma may result. In the presence of diabetes, operations may be performed with comparative safety so long as the diabetes is under control. It should be remembered, however, that the operative trauma will temporarily aggravate the diabetic state.

Emergency Operations.—These present a difficult problem. In infections and trauma, the needs of the body for insulin are increased, and the dosage must be adjusted accordingly. The operative risk in these patients is greatly increased. If a true emergency exists, every attempt should be made to control acidosis, but if the added risk is both necessary and appreciated, it may still be advisable to proceed with surgery even in the presence of ketosis.

The acute abdominal case is of special interest. In many of these, e.g., acute appendicitis, the symptoms are milder in the diabetic. It should also be appreciated that in patients in diabetic acidosis or impending coma, acute abdominal symptoms may develop, which may be easily confused with those of appendicitis and pancreatitis.

Localized collections of pus in the diabetic patient may be called a diabetic emergency. The presence of retained pus has an adverse effect upon the diabetes, making its control difficult or impossible. As drainage operations outside the abdominal cavity are of relatively short duration and can be done under light anesthesia, operation can be undertaken without delay, even in the presence of uncontrolled diabetes.

Preoperative Care.—It is important that the glycogen and protein reserves of the liver of the diabetic patient be augmented by a diet containing adequate amounts of carbohydrate and protein. Because of the widespread arteriosclerosis, a careful evaluation of the cardiac and renal status should be made before any elective operation.

In general, protamine insulin is more difficult to use in the immediate preoperative and postoperative periods, and so a change should be made to the quick-acting crystalline form which permits more exact regulation. On the

PREOPERATIVE AND POSTOPERATIVE CARE

day of operation the caloric needs of the patient can be met by intravenous glucose, which should be covered by insulin (1 unit of insulin per 5 Gm. of glucose). No attempt should be made to render the urine completely sugar-free because of the dangers of hypoglycemic reactions. It is safer to maintain a moderate degree of hyperglycemia in the preoperative and postoperative periods than to risk the development of insulin shock.

Anesthetic.—In the selection of an anesthetic, three factors should be kept in mind:

1. **Toxicity.** General anesthetics, especially chloroform and ether, should be avoided if at all possible, because there is a risk of producing fatal damage to a glycogen-depleted liver.

2. **Length of action.** The sooner after operation the patients are able to take carbohydrate food, the easier will be the management and the less likely the development of ketosis.

3. **Liability to produce postoperative vomiting.** The anesthetic of choice, therefore, is one with a low toxicity, rapid elimination, and a low incidence of nausea and vomiting. For operations of a minor nature, nitrous oxide and oxygen should be used. Even in abdominal surgery these gases combined with curare seem free from deleterious effects. For major surgery, both nitrous oxide supplemented with curare and spinal anesthesia are the agents of choice.

Postoperative Care.—An adequate fluid intake is important for the diabetic patient. During the operative period blood and saline may be used as necessary. Glucose, if required in the postoperative period to meet caloric requirements, should be covered by insulin, though care should be taken to avoid hypoglycemia. Oral feedings should be given as soon as tolerated and increased until an adequate diet is attained.

The following routine may be used as a guide for the insulin and carbohydrate requirements for diabetic patients who are undergoing surgical procedures. It is most important that a clear description of the diabetic state, including the insulin requirements, should accompany the patient to the operating room so that intravenous fluids may be con-

tered by the necessary insulin. The standard form which is used at the Royal Victoria Hospital for this purpose is as shown in Table 6.

General Considerations.—

1. Other than emergencies, all operations, if possible, should be performed in the morning.

2. Use crystalline zinc insulin for the immediate postoperative period.

3. The diet should have contained at least 200 Gm. of CHO/day on the two days preceding the operation. There should be no acidosis, and the patient should be free from glycosuria in a 24-hour specimen of urine.

4. The blood sugar should be slightly elevated or within the normal range.

5. Less insulin will be required postoperatively if the operation reduces sepsis. The decreased insulin requirement is gradual and is usually not apparent for 12 hours.

6. Preoperative sedation and the choice of an anesthetic agent should be no different from those of the nondiabetic patient.

Specific Considerations.—

1. **Day of operation.**—major surgery: If the patient has been on protamine zinc insulin, give no insulin and no breakfast.

It is safer to place the patient on crystalline zinc insulin when the operative procedure is expected to be prolonged or stormy, or when in a major one, when the convalescence is expected to be prolonged or stormy, or when in doubt. The dose of insulin required can be calculated by estimating the preoperative requirements per 10 Gm of carbohydrate, i.e.:

Protamine zinc = $\frac{2}{3}$ crystalline zinc
 NPH insulin = $\frac{1}{3}$ crystalline zinc
 Patient's intake of carbohydrate was 250 Gm
 Patient's insulin requirement was 77, 21
 $\frac{77}{250} = \frac{12}{100}$

Therefore the amount of $\frac{12}{100}$ insulin was 48 units
 or 10 units of insulin for every 50 Gm of glucose

Fractional urines should be used to help judge insulin requirements.

2. On return from the operating theater, give 1,000 ml of 5% glucose-saline intravenously, with the number of units of $\frac{12}{100}$ insulin subcutaneously as estimated above.

3. No oral feedings should be given during the first 24 hour postoperative period.

TABLE 6
FORM ACCOMPANYING DIABETIC PATIENT TO OPERATING ROOM

Patient's last name				First		Age	Sex	Case No
Duration of diabetes		Mild	Moderate	Severe	Stable		Unstable	
Complications of diabetes								
Maintenance		Diet			P.	F.	C	
Maintenance		Insulin						
Preoperative preparation								
Date of last blood sugar		AC			PC		PCL	
Time of last urinalysis		Sugar				Acetone		
Suggested fluid in O R and recovery room								
Suggested insulin coverage				(1) In bottle			(2) SC

ANESTHETIC SECTION

Time		Type of anesthetic		Duration	
Fluids in O R type ml		Time of infusion	Beginning	End	Insulin in O R
Fluids in recovery room ml		Time of infusion	Beginning	End	Insulin in R R.
TOTAL FLUID		ml		TOTAL	
Time discharged			Anesthetist		
Remarks					

4. In the second 24-hour period postoperatively, give 20 Gm. fluid feedings every 3 hours for six feedings. Preceding every second feeding, the required number of units of CZ insulin should be given.

5 The diet on the first day of three meals should be protein 70 Gm., fat 50 Gm., and carbohydrate 150 Gm., assuming the preoperative diet had been protein 70 Gm., fat 50 Gm., and carbohydrate 250 Gm

Minor Surgery, and Surgery Carried Out Under Local Anesthesia—

1. The preoperative insulin dosage is the same as that described above under major surgery

2 On return from the operating theater, give 1,000 ml. of 5% glucose saline, intravenously, with 16 units of crystalline zinc insulin, subcutaneously

3. At 6 P.M., 8 P.M., and 10 P.M. on the day of the operation, give 200 ml of orange juice

4. Give 12 units of insulin before the 8 P.M. feeding, i.e., at 7:30 P.M

5. On the following day, three meals may be instituted and preoperative control re-established

Chapter 6

Injuries Due to Physical Agents

Thermal, Irradiation, Electric, and Chemical Trauma

Hamilton Baxter, MD

THERMAL BURNS

The prevalence of injuries from heat may be realized when it is shown that nearly 8,000 people in the United States and an estimated 60,000 in the world die each year from this cause. These figures become insignificant when compared with the hundreds of thousands of people who are hospitalized for this type of injury and suffer various degrees of disfigurement each year. When one calculates the staggering number of man-hours of work lost to industry, the hospital beds required, and the hours of medical and nursing care needed, it is indeed remarkable that so few preventive measures have been adopted. The widespread use of noninflammable or fire-resistant clothing by the civilian population would greatly reduce the number of cases requiring treatment on this continent each year.

Between World Wars I and II certain marked physiologic disturbances in the burned patient were observed. First the deficiency of electrolytes and fluid was noted. Then it was shown that plasma was extravasated into the burned area with resultant hemoconcentration and that plasma administered intravenously was beneficial. Finally the infective phase of burns was recognized and various therapeutic measures advocated for treatment. As a result of the large number of burns suffered by civilians and military personnel in World War II, in-

tensive research was carried out, and several major advances in therapy resulted. These may be summarized as follows:

- 1 The development of improved methods of treating shock and hemoconcentration
- 2 The wide adoption of the occlusive pressure dressing and the exposure method
- 3 The dermatome, which enabled surgeons to obtain accurately and easily any thickness and amount of skin grafts desired
- 4 The discovery and use of sulfonamides, penicillin, and newer broad-spectrum antibiotics

- 5 Improvement in methods of nutrition
- 6 The resurfacing of granulating areas at the earliest possible time, which automatically prevents most of the chronic sequelae of burns

The original classification by Dupuytren of the severity of a burn into six degrees was simplified, for reasons of practical convenience, to include only the following three divisions: *first degree burn*, which causes reddening of the skin; *second degree burn*, which involves the deeper layers, although regeneration is possible from the remaining hair follicles, sweat, and sebaceous gland ducts; and *third degree burn*, which destroys the entire skin and any or all deeper structures, including bone. Thus, in modern terminology, the third degree burn includes the fourth, fifth, and sixth classifications by Dupuytren. Healing of

INJURIES DUE TO PHYSICAL AGENTS

A

B

C

Fig. 30—A, A comparison is made of the changes in per cent surface area of the head and extremities between children and adults
 B, Baskow's method of calculating the extent of burns
 C, "Rule of Nine" proposed by Wallace

a first degree burn is complete in a few days, while one of second degree will require about two or three weeks, depending on the number and viability of epithelial structures remaining. A variable amount of scar formation results. The third degree burn, if small, may heal by epithelial ingrowth from the edges or by contracture, but large areas should be skin grafted as soon as the depth of the burn is evident. Although a number of methods for determining the depth of thermal burns have been proposed, the most reliable test is that of visual inspection at intervals, due allowance being made for the region of the body and the usual hair distribution.

The Berkow table for adults and its modification for children should be used to calculate the percentage of the body surface burned, so that the amount of plasma and fluids to be administered may be determined. For example, the percentage of surface area of the head of a 1-year-old child is twice that of a 15-year-old child. As an alternative method Wallace has proposed the "Rules of Nine" and divides the various extremities and the anterior and posterior aspects of the trunk into areas of 9% or multiples thereof. By either method a rough estimate of the areas of first, second, and third degree burns should be charted for comparison with the final outcome. Very young and aged individuals are more liable to suffer from shock than healthy adults. Burns of the face, abdomen, and buttocks in children, although limited in area, sometimes result in shock. Severe burns of more than 50% in patients over 50 years of age very frequently result in death. For every decade over 50 years of age, the percentage of body burn which will cause a high mortality decreases markedly. Patients over 60 years of age may die from a relatively minor burn because of coexisting conditions, such as cardiac, pulmonary, renal, or arteriosclerotic disease. Malnutrition or anemia may require treatment as well as the burn.

Physiologic Derangements

Shock.—Immediately following a burn, pain is experienced which varies with the type of injury. This may cause syncope or death within an hour or two despite prompt therapy.

Blood Flow.—Due to the painful sensations, there is a brief period of blanching of

the skin followed by vasodilatation of the vessels of the skin and subcutaneous tissue. Unless charring has occurred, there is a marked increase in capillary permeability with extravasation of plasma, particularly the albumins, into the interstitial spaces. The more extensive the burned area, the greater will be the amount of plasma lost from the vascular system. This results in hemoconcentration, which is well established in a few hours and is so characteristic of thermal burns.

Loss of Plasma and Increase in Lymph Flow.—The protein content of the escaped fluid is estimated at about 4%, and from 1.4-2.3 Gm. of nonprotein nitrogen may be lost per square inch of burned surface in 24 hours. The albumin/globulin ratio of bleb fluid is greater than that of plasma. The flow decreases as the burn heals. The lymph return is increased from a burned area, and this flow is not reduced by an occlusive burn dressing. No definite toxic substance has been found in the lymph returning from an area of thermal burn in man. For several days the total lipids, total cholesterol, and fatty acids are markedly elevated in lymph flow from a burned area but remain unchanged on the unburned side.

Anemia.—Immediately following the burn there is local heat destruction of red cells in the area of burned skin and subcutaneous tissue. This anemia is temporarily masked by the hemoconcentration which occurs. Cope has shown that in extensively burned patients not over 10-12% of the red cell mass was destroyed by the initial thermal trauma. While large amounts of whole blood may not be required in treatment of burn shock during the first 48 hours, it is necessary to give frequent transfusions to almost all severely burned patients after the first week. Increased fragility of red cells, reduced synthesis of hemoglobin, and bleeding from the burn wound contribute to the progressive anemia which continues until the granulating areas are covered with skin grafts and infection is overcome.

Permeability.—The burned surface permits flow of diffusible substances in either direction. Penicillin, Aureomycin, erythromycin, and other antibiotics are present in the plasma exuding from the burned surface in amounts which would encourage bacteriostasis. Al-

INJURIES DUE TO PHYSICAL AGENTS

though bacteria do not invade intact epithelium of a burned surface even if coagulated, once this defense is broken, they may cause local inflammation or bacteremia if favorable conditions arise

Fluid, Colloid, and Electrolyte Imbalance in the Burn Wound.—The burn wound draws water, protein, and electrolytes from the injured and permeable capillaries into the extravascular spaces, and thus the wound swells with edema. If the burn is limited, the patient will survive without special fluid therapy. On the other hand, unless early and adequate replacement therapy is given in extensive burns, the patient may die. Burn trauma not only increases the permeability of the capillary membranes so that much plasma is lost into the wound, but the nervous reflex mechanism controlling blood flow is disrupted so that increased arterial flow to the burned area occurs, and this in turn augments the filtration of fluid into the wound. The burn wound fluid has a much higher concentration

of plasma protein than that of normal tissue and lymph. Following a mild burn the protein concentration of bleb fluid may be no greater than 3 Gm. % and after a moderate burn no more than 4 Gm. %. A severe burn rarely gives a concentration of over 4.5 Gm. %. The rate of edema formation is relatively proportional to the severity of the burn. With increasing tissue pressure, the lymphatic flow is at first rapidly increased, but as edema pressure reaches a maximum, the lymph flow decreases but does not return to normal. In burns in human beings, edema appears to reach its maximum between the 36th and 42nd hour. Apparently capillary permeability has increased sufficiently so that filtration no longer exceeds resorption of fluid. The cycle of changes is shown in Figs 31-38

Pathology.—The thermal agent may produce various degrees of injury: erythema, edema, or even necrosis. These three types of damage may be present in different areas of a burn. Flame burns are likely to produce

Fig 31—The normal protein levels of plasma and interstitial fluids are shown, as well as the movement of extracellular and intracellular electrolytes

Fig 32—The initial effect of the burn upon protein concentration of plasma is an increase. The protein concentration of the burn wound fluid, although much higher than that of normal tissue fluid and lymph, rarely rises above 4.5 Gm

Fig 33—The part of the plasma protein which did not pass with the plasma fluid into the burn wound remains in circulation, and its elevated colloid osmotic pressure draws fluid from the unburned tissue into the blood stream, so that a dilute plasma is the second phase of protein and fluid redistribution after a burn. During the initial phase (Fig 32), the concentrated plasma could not resorb fluid from the burn wound because of the damaged capillary membrane

Fig 34—Here the wound has continued to swell. More fluid has been drawn from the interstitial space into the blood stream with a rise of colloid protein in the interstitial fluid. Water is drawn from the cells into the extravascular space and with it the intercellular electrolytes, potassium and phosphorus are believed to pass out of the cells. Kidney function ceases and permanent renal damage may occur. Death may occur partly from dehydration, partly from anoxia

Fig 35—If the burn is not extensive, redistribution of fluid and colloid occurs. With healing of the capillary membranes, leakage into the wound diminishes, and protein concentration of the fluid escaping into it is diminished. Lymph flow into the blood stream continues, and the wound edema subsides. The plasma recovers its normal pattern, and the cells regain their normal content of water and electrolytes

Fig 36—This shows the effect of using whole plasma alone. The amount of plasma given equals the weight of fluid lost in the burned area. It is good but not ideal therapy since there are enough water and electrolytes but too much protein. Administration of whole blood alone gives somewhat similar results

Fig 37—When sufficient electrolyte solution is given to refill the circulating plasma volume the fluid distributes itself generally. The protein content of all spaces is diluted. Widespread edema occurs, and pulmonary edema may develop. The cardiovascular and renal functions tend to fail.

Fig 38—A mixture of colloid and electrolyte solutions is injected into the blood stream in such concentration and volume as to replace completely the water, electrolytes, and protein lost in the wound. Much or all of the electrolyte solution may be given by mouth if desired. This provides ideal therapy for burn shock

Figs 31-38—(See opposite page for legends)

dry necrosis, while steam, hot water, and other fluids tend to cause a moist necrosis. A *first degree burn* is marked grossly by hyperemia, and if sections are examined, a mild exudate of serum and leukocytes will be found. Desquamation is followed by regeneration and healing. A *second degree burn* is characterized by vesication and various degrees of injury to the dermis. Edema of the skin occurs with bleb formation and hyperemia of the deeper elements, and necrosis of part of the dermis. Regeneration occurs from the remaining hair follicles, sweat, and sebaceous glands. The *third degree burn* is marked by necrosis of the whole thickness of skin. An eschar forms which sloughs off, leaving an ulcer. Epithelial regeneration can occur only from the margins of the burn. This is the type of burn in which severe contractures occur if skin grafting is not performed at an early stage.

Systemic Manifestations

Primary shock is of neurogenic origin and results in generalized vasomotor collapse. It is seen shortly after injury and is characterized by pale, clammy, moist skin, shallow respirations, and a weak pulse. In severely burned patients, death may occur from this cause before a physician can institute treatment, or even in spite of it.

Secondary shock occurs subsequent to primary shock, lasts for 2-3 days, and is characterized by hemoconcentration and the escape of plasma into the tissues.

Due to the increased red blood cell concentration and increased viscosity of the blood, there is decreased cardiac output and decreased blood flow to certain vital organs. The liver and kidney are particularly affected, and due to decreased blood flow, renal function may be drastically reduced so that the tissues and tubules of the kidney may never regain their function, and death from uremia may result.

The normal functions of the liver are retarded when there is an inadequate supply of blood and oxygen, so that glycogen cannot be stored, and deamination is prevented.

Lungs.—Direct exposure to flame or hot gases may cause some injury to the respiratory tract, usually only as far as the trachea. The bronchiolar epithelium is more likely to be

injured by chemically irritating gases. Carbon monoxide poisoning and lowered oxygen content of air may become major lethal factors when fire occurs in enclosed spaces. Early tracheostomy is important if there is evidence of pulmonary injury due to heat or irritating gases.

Adrenals.—Following burns as well as other forms of stress, there is adrenal hyperactivity mediated through the pituitary with increased output of adrenal hormones, as revealed by eosinopenia and a rise in output of urinary ketosteroids. In certain systemic conditions the adrenal may not be able to react adequately, with subsequent collapse.

Thyroid.—In chronic burn patients with extensive granulating areas, hyperactivity of the thyroid gland has been postulated. There is a rapid pulse, considerable weight loss occurs, and the basal metabolic rate may be greatly increased. In some patients a basal metabolic rate of plus 40 has been recorded. However, this is not due to increased activity of the thyroid gland but to increased oxygen consumption caused by proliferating granulation tissue. It disappears when the burn heals or is skin grafted.

Acute toxemia overlaps secondary shock and lasts for 7-10 days. Those who survive secondary shock and subsequently die usually do so in this period. Whether it is due to toxic substances or to physical changes in the circulating blood or is caused by anemia and septic infection is uncertain. When extensive second and third degree burns of from 20-80% of the body surface occur, death frequently results in spite of intensive colloid and electrolyte replacement therapy. In elderly individuals, death may be due to the additive effect of coincident cardiac, renal, pulmonary, or systemic diseases, together with the thermal burn. However, in young, previously healthy adults, a syndrome characterized by disturbance of electrolyte levels, marked mental depression, and peripheral vascular collapse without evidence of invasive clinical infection from the burned surface may occur. Various causes have been attributed to this syndrome, such as loss of function of the skin as an organ, toxic effects of undetected septicemia, or collapse of the pituitary-adrenal endocrine system. The

toxemia in burns is probably a manifestation of invasive infection and septicemia. At times this downward progression may be altered to complete recovery by combined autogenous and homologous skin grafting of granulating areas, adequate blood transfusions, and good nutrition. Nevertheless, in some patients the pulse becomes rapid and the skin cold and cyanotic, and hyperpyrexia may develop. Restlessness progressing to stupor and a final fall in blood pressure indicate approaching death.

Chronic sepsis is due to the retention of pus under dead skin or wound granulations and is eliminated by removal of eschar and skin grafting.

TREATMENT OF BURNS

First Aid

Minor Burns.—Very minor burns about the home, particularly in children, are the cause of much screaming on the part of the child,

Fig 39.—Marked emaciation which develops in patients with extensive third degree burns when skin grafting is delayed beyond the optimum period

In children, convulsions often precede the demise. Sudden respiratory failure may occur, and increased intracranial pressure with compression of the medulla oblongata has been found. Microscopically, severe interstitial edema and ganglion cell changes, most marked in the hypothalamus, have been noted.

anxiety to the parents, and frequent calls to the doctor. For psychologic reasons mainly, but also to protect the wound from trauma and to minimize discomfort, treatment should be initiated by the parent. The part should be cleansed, grease or other contaminants should be wiped away with absorbent cotton, and

INJURIES DUE TO PHYSICAL AGENTS

sterile gauze dressings lightly bandaged to the burned part. After a few days the dressing may be changed. The great majority will have healed, and the few deeper injuries may be treated by the doctor as required.

Serious Burns.—Emergency treatment should consist of wrapping the burned area in sterile (or clean) dressings, towel, sheet, or blanket and transporting the patient to hospital as soon as possible. Give morphine, 10-16 mg., subcutaneously or intravenously, as indicated.

Immediate Definitive Treatment

General Therapy.—

1 Sterile masks for attendants and patient if possible. Remove burned clothing and place on sterile sheet in dressing room or operating room. Take blood for hemoglobin, hematocrit, hemogram, blood proteins, and electrolytes. Ask or otherwise determine weight of patient.

2 Estimate extent of burn accurately, using Berkow's Table or the "Rules of Nine" proposed by Wallace.

3 If burn shock may be anticipated (15% of body surface or more in healthy adults, or 10% in babies, young children, or elderly persons), do not wait for signs of shock to appear, but give intravenous colloid or electrolyte solutions according to the following formula.

First 24 hours

(a) 1 ml./kg. for each 1% body surface burned of blood, plasma, or plasma substitute (give part whole blood and part plasma, dextran, or polyvinyl pyrrolidone).

(b) 1 ml./kg. for each 1% body surface burned of electrolyte solution physiologic saline.

(c) 2,000 ml. of 5% dextrose in water. The colloid and electrolyte solutions should be administered intravenously, using a large needle or a cannula inserted in the vein following a cut down. In the first 8 hours, one half the total estimated fluid requirements for the first day should be given, one quarter in the second 8 hours, and one quarter in the last 8 hours. If no vomiting is present the 2,000 ml. of 5% dextrose may be given by mouth, otherwise the intravenous route is used.

Second 24 hours

Reduce colloid and electrolyte requirements to one half the total amount for the first 24 hours. The 2,000 ml. of 5% dextrose in water is continued.

4 Obtain urine for *urinalysis*, insert Foley catheter in patients with burns of 15-20% or

over. Maintain hourly urine output of 25-30 ml. in adults and 15-25 ml. in children. Adjust rate of fluid administration to maintain this output.

TABLE 7
REQUIRED URINE OUTPUT FOLLOWING BURNS

AGE	ML. PER HOUR (AVERAGE)
4-7 years	25
7-10 years	30
10-14 years	33
Over 14 years	50

5. *Antibiotic therapy* should be commenced without delay. Large quantities of broad-spectrum antibiotics should be used. It has been shown that these are present in considerable quantities in the plasma escaping from the burned surfaces and that bacteriostatic levels are obtained against most hemolytic streptococci and micrococci, which predominate the bacterial flora of recent burns. An enhanced effect may be obtained by combining penicillin with streptomycin, or chloramphenicol with oxytetracycline. Subsequently, tetracycline with oxytetracycline may be chosen, the most effective and sensitivity tests to antibiotics of various bacteria obtained from the burn wound. The patient should be questioned regarding sensitization to antibiotics, and those known to cause reactions should not be administered.

6. *Oxygen* should be administered by nasal catheter, mask, or tent if there is evidence of burns of the mouth and larynx. Inhalation of steam or hot irritating gases may cause obstruction of the trachea or edema of the lungs. A tracheostomy may be necessary to facilitate aspiration of the bronchi. Pulmonary damage due to irritating gas or vapor may necessitate reduction in the total amount of fluid administered, electrolyte solutions being replaced in varying degrees by whole blood.

7. Give a booster dose of *tetanus toxoid* or 1,500 units of tetanus antitoxin.

8. It is generally agreed that the use of *corticotrophin* or *cortisone* should be limited to the treatment of very severely burned and critically ill patients during the early stages of the trauma. Remarkable recovery has occasionally been observed following an initial dose of 800 mg. of cortisone, which was reduced

rapidly to the usual therapeutic dose during the course of a few days

9. Following a minor burn, patients can usually take a fairly substantial diet by mouth. However, following an extensive burn, the patient may tolerate only a limited amount of fluid or soupy diet. In some instances vomiting occurs, and all fluids must be given intravenously. It may be necessary to provide continuous gastric suction by means of a nasal catheter for a few patients, because of persistent vomiting. In such cases, blood electrolytes should be determined at intervals and measures taken to restore normal levels of the various electrolytes.

Local Therapy.—The total area of a burn and some estimate of depth of injury should be carefully recorded, since these factors determine to a considerable degree the amount of plasma and electrolyte therapy administered. The fact should never be forgotten that *treatment of the general condition of the patient takes precedence over local care*, unless two teams are immediately available. Failure to observe this rule has permitted many patients to slip into irremediable shock while a perfect dressing was being applied. If at all possible, the patient should be taken to an operating room where, under aseptic conditions, the burned areas are cleansed and application of a dressing is carried out. Adequate doses of morphine are given, but general anesthesia is not employed. The local care of the burn wound is the same whether the exposure method or an occlusive dressing is to be applied. Gross dirt or oil is removed from the burned area with large quantities of warm sterile water and hexachlorophene, 1% cetrimide, or white soap on cotton balls or sponges. Blisters are drained, but the skin over them is not removed. Any loose tags or rolls of epithelium are removed with scissors. Cleansing is carried out with a minimum of trauma to the exposed dermis.

Despite the imposing list of over 70 methods of treating burns, it should be recognized that variations in treatment must be made because of the age of the patient, the location and depth of the burn, and the agent causing the burn. The purpose of any method of local treatment is to limit infection and minimize further skin damage. This may best be achieved

by promoting dryness and relative immobility of the burn wound. These conditions may be accomplished by one of two techniques generally used at present—the *occlusive dressing method* and the *exposure method*. Each has its own advantages and disadvantages and indications for use, depending upon the site and type of burn.

Occlusive Dressing Technique.—The burned surface is dressed with dry fine-mesh gauze or gauze impregnated with petrolatum or other bland ointment. After applying a number of layers of flat gauze dressings the whole is covered with a bulky layer of cotton waste which is held under moderate pressure by an elastic bandage or adhesive tape.* Plywood or plaster splints may be applied to prevent movement. The dressing is not changed for 7-14 days, depending on evidence of infection. This should be carried out in the operating room, with preparation having been made either to debride necrotic tissue or to apply skin grafts.

Advantages—

1. The dressing provides pressure on the burn wound, which may reduce *very slightly* the amount of fluid lost into the extravascular spaces.
2. The thick dressing provides protection from cold and bacterial or other contamination.
3. When thermal burns are combined with fractures, the dressing may be reinforced with splints or plaster, to provide protection for the combined injuries.

Disadvantages—

1. The dressings require much storage space and periodic resterilization.
2. Application of the dressing requires a moderate amount of time and trained medical personnel.
3. When the dressing is applied too tightly, it may cause a tourniquet effect or nerve damage with permanent injury to an extremity.
4. Respiratory movements of the thorax and abdomen are restricted.
5. Hyperthermia may be caused when a large area of the body is covered with the dressing.

*A large occlusive burn dressing, prepared in two sizes (18 x 18 inches and 18 x 36 inches) and manufactured commercially may be used if desired.

6. It must be removed to inspect the burn lesion at intervals.

7. In extensive deep second degree burns the plasma exudate may soak through after a few days and require a change of dressing to prevent ingress of bacteria from the outside.

Exposure Technique.—Apparently this method was first used at least 60 years ago, but did not gain many adherents at that time, probably because of the difficulty in controlling infection and also due to the fact that skin-grafting techniques were primitive and usually delayed too long after the burn. This resulted in suppuration, serious systemic reactions, and late burn contractures. Recent experiences with this method have shown that various parts of the body can be quite satisfactorily exposed by different methods of elevation or suspension, so that contact with bed clothing or other objects is prevented. The burned area is cleansed as in the occlusive dressing method but is left exposed to the air of the ward. Nursing care is concentrated on protection of the burned surface, and a bed-cradle, covered with a clean sheet and blanket if necessary, will help to keep the patient warm. The limbs are positioned to avoid contact with the bed clothing and to limit edema and are restrained to prevent cracks in the crust. This limitation of movement is achieved by a clove-hitch soft bandage applied to unburned parts of the limbs. In partial-thickness burns, a dry, brown crust forms in 48-72 hours, while the full-thickness burn caused by fire presents from the first a hard, dry eschar.

HEAD AND NECK.—The exposure method is particularly suitable for these areas and prompt healing occurs unless the burns are very severe. If the eyelids have been deeply burned, tarsorrhaphy should be performed early to avoid the formation of corneal ulcers; skin grafts are applied as soon as possible. Any discharge from the eyes, nose, or mouth is carefully removed at intervals. The neck should be kept in hyperextension. If the cranium or other bones of the body are exposed, multiple small drill holes should be made in the bone. Split skin grafts may then be applied when sufficient granulations have grown through the holes and proliferated.

UPPER EXTREMITIES.—Burns of the hand and forearm may be treated by keeping the elbow flexed and the hand elevated. When almost the entire upper extremity is involved, it is possible in most cases to support the limb by sterile linen slings or other supports at areas which are not seriously damaged. For example, the palm is frequently only slightly involved, and a sterile, padded support placed in it will aid in elevating the arm without jeopardizing healing of the hand. Suspension of the hand and arm may be obtained by passing steel sutures through the nails and attaching them to a spreader. If the fingers are deeply burned circumferentially, it is advisable to use the occlusive dressing method with the wrist extended and all joints of the fingers flexed to 30 degrees in the position of function. In certain cases of third degree burns, the eschar may be excised on the 3rd-5th day and skin grafts applied immediately.

THE TRUNK.—Only one side of the trunk may be successfully treated by the exposure method. With a cooperative patient it is possible to expose a burn involving the back, one side, and part of the abdomen by positioning the individual on one side. Circumferential burns of the trunk are not suitable for treatment by the exposure method.

GENITALIA AND PERINEUM.—These areas heal most successfully when treated by the exposure method.

Farmer has proposed that burned areas treated by the exposure method should be dusted with aluminum powder frequently until a dry eschar has formed. It was observed that the eschar was thinner and more pliable and permitted movement of joints better without cracking.

LOWER EXTREMITIES.—The method of fixation varies with the distribution of the burns. Children with burns of the buttocks and upper parts of the thighs tolerate a gallow's suspension splint very well. When the entire circumference of the legs has been burned, they must be elevated so that there is no contact with bedclothes. The feet and ankles are not involved in most burns of the lower extremities, and the weight of the legs may be supported by resting the feet on sponge-rubber pads, placed on an adjustable stand which may be raised to obtain complete exposure of the af-

fectured areas. In this fashion, burns of the legs up to the buttocks and perineum may be successfully treated.

Advantages—

1 Plasma loss from the surface of the burn is minimal after the crust forms. Formation of this usually requires 48-72 hours and occurs more rapidly in a cool room.

2 Infection is less common than with occlusive dressings, and the patients are more comfortable once the crust forms.

Disadvantages—

1. Circumferential burns of the trunk are not suitable for treatment.

2. Although superficial burns of the hands may be treated by the exposure method, it is advisable to use the occlusive dressing technique for deep burns of the hands and feet, since interference with blood supply to these extremities may occur by a contracture of the crust when the exposure method is used in deep burns.

Fig 41—A, Circumferential burns of both legs, mainly third degree. Dry, brown eschar separating just before skin grafting.

B, Posterior aspect of legs, following split thickness skin grafts from buttocks to ankles.

C, Anterior surface of legs showing skin grafting of thighs and lower legs shortly after healing of grafts.

3. There is less odor and fever, and smaller doses of narcotics and antibiotics are required. The patient's appetite and morale are better.

4. Reduction of infection and suppuration reduces the conversion of partial to full thickness skin loss. Fewer patients require skin grafting, and hypertrophic scar formation is decreased.

5. A minimal number of hours of nursing and surgical care are required after the crust forms unless skin grafting is necessary. The expenditure of bulky surgical dressings is eliminated.

Intermediate Treatment

(From 48 hours until separation of burn crust or beginning of skin grafting)

General—

1. *Fluid intake* from the 3rd day on should be kept at a sufficiently high level to provide for an adequate output of urine and insensible fluid loss as well as that from the burned surface. If signs of pulmonary edema develop, fluids should be curtailed.

2. *Blood electrolyte levels* should be determined at intervals and measures taken to correct either excessively high or low levels.

3. *Antibiotic therapy* should be continued, but changes in the agent employed may be necessary because of allergic response, development of bacterial resistance or impairment of bone marrow.

4. *Blood transfusions* Determine hemoglobin level frequently. After treatment of burn shock, the need for red blood cells depends upon the volume of these cells destroyed immediately by heat. It has been estimated that not more than 10-12% of the red cell mass is destroyed in extensively burned patients. Red cell loss occurs from cells made more fragile and hemolyzed, sludging of blood, and later on from bleeding from exposed granulations and débridement of slough. The hemoglobin should be maintained at 85% or higher.

5. *Urinalysis* at regular intervals. The Foley catheter may be removed when an adequate daily urine output has been maintained for a number of days.

6. *Nutrition* As a result of lowered food intake, deranged nitrogen metabolism, fever, and infection, an individual suffering from extensive burns loses weight rapidly, and there is marked wasting of muscles. To combat this, a diet high in protein, calories, and vitamins should be given as soon as tolerated. A suitable diet consists of 150-200 Gm protein, 250-300 Gm of carbohydrate, and 100 Gm. of fat. Sulfur-containing foods should be provided, as well as large amounts of vitamin C and vitamin B complex. If vomiting is present in the early stages, intravenous therapy must be substituted until about the 3rd post-burn day, when most patients can take food. Blocker has employed a small pump to force a semifluid diet continuously through a nasal catheter which is inserted into the stomach. Mildly burned patients can tolerate a higher food intake than those severely burned.

7. *Hyperthermia* Remove occlusive dressings if used, and place patient in oxygen tent with thermostat set at lowest temperature. If fever remains high, apply ice packs to unburned areas. Remove ice bags before temperature reaches normal so that hypothermia will not occur.

8. *Hormone therapy* Intramuscular injection of 10-50 mg of testosterone daily has been found of value in improving the general condition of the debilitated burn patient. In

spite of earlier favorable reports, corticotrophin and cortisone should be employed only in the treatment of critically ill patients and then in large doses. It is generally agreed that they do not significantly depress formation of granulation tissue, impede the "take" of autogenous skin grafts, or prolong the life of homologous skin grafts in man.

9. *Active exercise* Planned bed exercises are most important in reducing nitrogen loss, maintaining vital capacity of lungs, and in improving morale. Less severely burned extremities should be exercised first, for while active movement is important, it should not interfere with healing of raw areas. Manipulation and passive stretching are condemned. Hydrotherapy is not indicated unless the stage of healing of the part can tolerate soaking in water.

It should not be forgotten that a severely burned individual requires endless encouragement and freedom from financial worry concerning his family or relatives.

Local.—

1. When a burn has inflicted a partial skin loss, the normal skin regeneration will finally separate the crust and expose a healed surface. This occurs in the average case from the 10th-14th day in superficial burns, and in deep second degree burns from the 14th-28th day. In third degree burns the depth of the burn may frequently be recognized after a few days, when the eschar becomes translucent so that the subdermal fat may be seen. The eschar also sinks below the level of the surrounding skin, which has been less seriously damaged. If the heat-coagulated skin is allowed to remain too long, pus will collect beneath it. This should be removed as soon as observed, by cutting away the eschar over the collection of pus and applying wet dressings to the exposed granulating area. When cracks develop in the dry crust, usually about joints, the area on either side of the crack should be excised and wet dressings applied to the raw base in preparation for skin grafting.

2. *Débridement.* Removal of third degree burn slough may be carried out by either surgical excision or various types of wet dressings. Surgical excision causes considerable blood

loss, and if large areas are removed, the patient's general condition may be adversely affected. The use of Dakin's solution, pyruvic, or phosphoric acids for chemical débridement of slough is uncommon, since enzymes such as streptokinase, streptodornase, trypsin, collagenase, and proteinase are now used for the enzymatic débridement of heat-denatured skin. The latter two enzymes do not damage viable cells of the skin or cause untoward reactions in patients, other than a slight increase in the amount of fever.

Late Treatment

(From beginning of skin grafting until completion)

Prior to skin grafting the hemoglobin should be at least 85% or higher, and transfusions should be administered as required to achieve this level.

1 When the burned area is relatively small and obviously third degree, it is sometimes advisable to excise the burned tissue completely and apply a split skin graft immediately. The period of hospitalization in selected cases is reduced to a minimum.

2 When large areas of slough have been débrided, either surgically or by enzymatic débridement, it is advisable to apply a pressure dressing for several days, so that a firm bed of granulating tissue will be prepared for the reception of the skin graft. If culture of the burn wound reveals the presence of pseudomonas or proteus which interferes with the "take" of skin grafts, ointments, or wet dressings containing neomycin or polymyxin applied for a few days are effective in overcoming these bacteria.

3 Full-thickness burns of 30% or more of the body surface will cause rapid deterioration of the general condition of the patient. In such patients the use of homografts of skin should be considered to increase the patient's chance of survival and reduce the size of the parasitic burn wound with minimal disturbance to the patient. The *alternate strip method* of applying a narrow autograft of skin, followed by a wider homograft until the granulating surface is covered, permits closure of large granulating surfaces without the subsequent breakdown and sloughing of the homograft which occurs when

homografts only are used. This may be achieved with autografts $\frac{1}{2}$ " wide alternating with strips of homograft $\frac{1}{2}$ " wide. The epithelium of the autograft proliferates and spreads across the dermis of the degenerating homograft. Thus, by making the patient's own skin extend coverage of granulating areas by proliferating over homografts, it is possible to obtain sufficient autografts of skin for resurfacing of critical areas such as the hands, face, and flexor surfaces of joints, while covering other areas with alternate strip grafts. Any granulating area over 2" in diameter is worth skin grafting. Even smaller wounds should be resurfaced when they are situated near joints, in areas where contractures may form, or on cosmetically important regions.

4. With early and adequate skin grafting, contractures of the extremities, neck, lips, and eyelids which caused such hideous deformities in neglected patients will no longer occur. The later plastic treatment of healed but scarred areas, in which sloughing of tendons or parts of the ears, the nose, or other features has occurred, is carried out by means of pedicle flaps, Z-plastics, or further skin grafting. Tendon grafts, cartilage, and bone grafts are inserted as required.

COMPLICATIONS OF BURNS

Many of the complications of burns, such as contractures of joints, distortion of tissues about the neck, mouth, nose, and eyelids, may be avoided if early and adequate skin grafting is performed. Curling's ulcer of the duodenum was found in 2% of burned patients and occurred more frequently in those with extensive burns. The condition was not diagnosed until marked epigastric pain or an acute gastrointestinal hemorrhage developed. Conservative medical treatment of the bleeding ulcer is advised unless operation is necessary to save life. Marjolin's ulcer is rarely seen now, due to improved methods of treatment of thermal burns. Corneal ulcers may be prevented by suturing of the upper and lower lid margins together, and skin grafting the burned surface as soon as possible. Loss of tendons may often be prevented by early coverage of the region with split grafts or a pedicle flap. Hypertrophic scars following thermal burns are probably less frequently seen, since newer

Fig 41—A and B, Explosion of magnesium incendiary bomb in hand of factory employee, with charring of hand and extensive third degree burn of arm, face, and opposite hand.

C, Result following thick split skin grafting of arm and face with scalp graft to reconstruct eyebrow. The exposed bones of the forearm were wrapped in a pedicle flap to withstand the pressure of an artificial hand.

INJURIES DUE TO PHYSICAL AGENTS

methods of treating burns have been developed. This condition may be defined as an excessive production of fibrous tissue within the limits of the wound, which gradually disappears after a few months. On the other hand, a keloid is due to an excessive production of fibrous tissue not only within the limits of the wound, but with invasion of the surrounding normal skin, which may assume considerable proportion in both linear extent and thickness. The treatment of large areas of keloid following burns is by excision and skin grafting. Immediately after healing of the skin graft, adequate roentgen or radium therapy is necessary to prevent recurrence, particularly in the margins of the skin graft.

CHEMICAL BURNS AND INJURY

Following injury with strong acids and alkalis, the affected areas should be washed with copious quantities of water as soon as possible to dilute and remove the chemical before reaction with the tissue and heat production can occur. The following solution which can be used as a buffer for either type of burn should be kept available, particularly in industries where strong acids and alkalis are used: monobasic potassium phosphate (70 Gm) and dibasic sodium phosphate (150 Gm) in water (850 ml). The burn should be washed with the solution, and compresses be applied every half hour for 12 hours. It is nonirritating and does not injure the eyes. Following neutralization of the acid or alkali, routine burn therapy procedure may be continued. Burns from hydrofluoric acid must be immediately washed with water and covered with magnesium-oxide cream. Powdered lime should be wiped away carefully before water is used. Routine burn treatment is then given.

Phosphorus powders should be brushed off before applying water to the part. Burning phosphorus in contact with tissue should be treated by plunging the part in water immediately. The heat of burning phosphorus, and not the acids formed during combustion, causes the deep tissue coagulation and damage seen in these burns. The phosphorus is then scraped off carefully. The area should then be washed with a solution of sodium bicarbonate (2 tablespoons to a pint of water) followed by a 1% solution of copper sulfate, which will

coat any remaining particles with a protective layer of copper phosphide. Regular burn dressings are then applied. Following severe white phosphorus burns common in wartime, systemic therapy should be started immediately. Methionine should be given in glucose saline (100 mg./L.) to minimize liver damage. Isotonic solution made up of two thirds saline and one third sodium bicarbonate should be given by mouth. Adequate amounts of calcium and vitamin K should be supplied. Surgical excision of necrotic skin and deeper tissue and subsequent skin grafting of the defects are frequently necessary.

Magnesium, which burns at intense heat, approximately 3,500° C., causes deep destruction should a flare or incendiary missile explode accidentally. Following removal of any remaining metal and grossly charred tissue, a burn dressing should be applied until final demarcation of necrotic tissue occurs and reparative treatment may be started.

Mustard gas causes blistering and deep destruction of skin. Contaminated clothing should be removed and liquid, such as moisture on the skin, should be absorbed by dry gauze. Any remaining gas or liquid should be neutralized by Dakin's solution. Subsequently the area should be washed with soap and water, dried, and a burn dressing applied.

Lewisite, which contains arsenic, acts rapidly and causes intense irritation of the skin, so all contaminated clothing should be removed and treatment started as soon as possible. BAL (British antilewisite or dimercaprol, USP) has been used with considerable success. An intramuscular injection of 3 ml of an oil solution is administered at the earliest possible moment and repeated every 4 hours for 4-5 doses. The total dose should not exceed 35 mg./kg. body weight during a 36-hour period. Locally, lewisite may be neutralized with hydrogen peroxide, followed by washing with soap and water. Skin blebs which contain arsenic should be drained and regular burn dressings applied.

ELECTRIC BURNS

Following a severe electric shock most patients are unconscious, and about three fourths require artificial respiration. This must often be continued for some time, and the heart

into the body and quite frequently involves muscle and bone, since the blood vessels provide an excellent path for conduction of electricity. In severe electric burns when there is surface charring and probably deep damage, it is advisable to wait until slough or sequestra have separated to avoid loss of salvageable tissue and risk of hemorrhage. Granulating areas may be resurfaced with skin grafts or pedicle flaps as indicated. Extremities which have been charred or show incipient gangrene should be amputated before infective or toxic symptoms appear.

RADIATION INJURY

Acute Total Body Radiation—Explosion of an atomic bomb by military intention may be expected to produce about 15% of casualties suffering from radiation injury alone. The problems of triage are complicated by the fact that the sensitivity of man to massive total body radiation is not known. It is generally estimated that 400 r constitutes LD_{50} in man, but some will succumb to 200 r, while others will survive high dosage. Estimation of the amount of radiation received, by a dosimeter, not completely reliable, since it or part of the body of the individual may be shielded. In general those beneath the hypocenter of the bomb may be assumed to have received a heavier dose of radiation than others a thousand yards or more toward the periphery. Clinically, patients suffering from acute radiation syndrome may be divided into three groups:

Group 1.—These have received supralethal dose and recovery is improbable. Vomiting starts early, or in a few hours, followed by shock, stupor, and death in a few

to survive, it
and the pre-
R.

2. Hemorrhage, mainly due to profound thrombocytopenia

3. Anemia due to hemorrhage, increased rate of destruction of red blood cells, and lack of production of red blood cells by the bone marrow.

4. Disturbance of fluids, electrolytes, and acid-base balance by anorexia, vomiting, diarrhea, and fever. Although pretreatment by various measures will reduce the mortality in acute radiation injuries, no specific therapy is available as yet which is effective when administered following exposure. The only methods available at present are antibiotics, blood transfusions, and other supportive measures until regeneration of bone marrow occurs.

Acute Localized Radiation Injury.—Individuals employed in atomic energy plants or exposed to radioactive substances, x-ray machines, or fluoroscopes in hospitals or industrial laboratories may receive large doses of ionizing radiations over a limited area of the body. The hands are particularly liable to suffer. Early symptoms are edema and erythema, which become more intense in a few days. Vesicles form and may coalesce to form large blebs. Moderate or severe pain may be present. The injured area should be covered with a bland ointment, gauze, and dressing which reduce pain. Infection may be prevented by adequate antibiotic therapy. Depending upon the dosage of radiation received and the resistance of the tissues, the skin and deeper tissues may heal or slough. Separation of slough should be awaited, when skin grafts may be applied. Thus an apparently doomed finger may be saved from amputation. However, because of the effect of acute radiation in causing sclerosis and obliteration of blood vessels, the injured skin will undergo more rapid atrophic changes than it will with small dosage or chronic exposure to radiation. To avoid ulceration or neoplastic changes, it may become necessary to excise all degenerating areas and "recoat" them with a fresh, healthy thick skin graft.

Chronic Radiodermatitis.—This may result as a sequel to acute injury or from the cumulative effect of repeated small doses of radiation. Telangiectasia, atrophy of skin, depigmentation, ulceration, or keratoses may be present in any combination. Cancer may finally appear

must be functioning. Fibrillation or arrest of the heart requires treatment by cardiac massage within 5-10 minutes and may be attempted if conditions are favorable. A fibrillating heart must be stopped by a shock from the defibrillator and then restarted. Once the patient has been resuscitated, shock should be

treated in the usual way to bring the blood values to normal levels.

The frequency of these burns is decreasing because of the increased safety of construction of various electric appliances. They differ considerably from thermal burns, in that necrosis of tissue follows the path of the current deep

Granulating areas may be resurfaced with skin grafts or pedicle flaps as indicated. Extremities which have been charred or show incipient gangrene should be amputated before infective or toxic symptoms appear.

RADIATION INJURY

Acute Total Body Radiation—Explosion of an atomic bomb by military intention may be expected to produce about 15% of casualties suffering from radiation injury alone. The problems of triage are complicated by the fact that the sensitivity of man to massive total body radiation is not known. It is generally estimated that 400 r constitutes LD₅₀ in man, but some will succumb to 200 r, while others will survive high dosage. Estimation of the amount of radiation received, by a dosimeter, is not completely reliable, since it or part of the body of the individual may be shielded. In general those beneath the hypocenter of the bomb may be assumed to have received a heavier dose of radiation than others a thousand yards or more toward the periphery. Clinically, patients suffering from acute radiation syndrome may be divided into three groups.

Group 1—These have received supralethal dosage and recovery is improbable. Vomiting starts immediately or in a few hours, followed by diarrhea, prostration, and death in a few days.

Group 2—A moderate amount of exposure has been received and survival is possible. Vomiting occurs on the day of exposure and subsides in 24 hours. There is a reappearance of symptoms in 1-3 weeks.

Group 3—Sublethal dosage has been received and survival is quite likely. There is no vomiting on the day of exposure and only mild symptoms occur subsequently.

In those who have a chance to survive, it is important to direct therapy toward the prevention or treatment of the following:

1. Infection

2. Hemorrhage, mainly due to profound thrombocytopenia.

3. Anemia due to hemorrhage, increased rate of destruction of red blood cells, and lack of production of red blood cells by the bone marrow.

4. Disturbance of fluids, electrolytes, and acid-base balance by anorexia, vomiting, diarrhea, and fever. Although pretreatment by various measures will reduce the mortality in acute radiation injuries, no specific therapy is available as yet which is effective when administered following exposure. The only methods available at present are antibiotics, blood transfusions, and other supportive measures until regeneration of bone marrow occurs.

Acute Localized Radiation Injury.—Individuals employed in atomic energy plants or exposed to radioactive substances, x-ray machines, or fluoroscopes in hospitals or industrial laboratories may receive large doses of ionizing radiations over a limited area of the body. The hands are particularly liable to suffer. Early symptoms are edema and erythema, which become more intense in a few days. Vesicles form and may coalesce to form large blebs. Moderate or severe pain may be present. The injured area should be covered with a bland ointment, gauze, and dressing which reduce pain. Infection may be prevented by adequate antibiotic therapy. Depending upon the dosage of radiation received and the resistance of the tissues, the skin and deeper tissues may heal or slough. Separation of slough should be awaited, when skin grafts may be applied. Thus an apparently doomed finger may be saved from amputation. However, because of the effect of acute radiation in causing sclerosis and obliteration of blood vessels, the injured skin will undergo more rapid atrophic changes than it will with small dosage or chronic exposure to radiation. To avoid ulceration or neoplastic changes, it may become necessary to excise all degenerating areas and "recoat" them with a fresh, healthy thick skin graft.

Chronic Radiodermatitis.—This may result as a sequel to acute injury or from the cumulative effect of repeated small doses of radiation. Telangiectasia, atrophy of skin, depigmentation, ulceration, or keratoses may be present in any combination. Cancer may finally appear.

INJURIES DUE TO PHYSICAL AGENTS

It should be stressed that such areas should be excised and skin grafted before neoplastic changes have developed.

Acute Radiation Syndrome.—It has been clearly established that radiations produce mutations and that, in general, mutations are harmful. It is difficult to estimate the extent of damage which will develop in future generations after mutant genes are induced by radiations. Most geneticists agree that the potential danger is great. It has been suggested that not

more than an average total lifetime dose of 10 r of man-made radiation should be administered to the reproductive cells. At the present time, about 3 r, on the average, are used for medical x-rays. Background radiation accounts for about 3 r, and the fall out from weapon-testing has been estimated at approximately 0.5%. The medical profession should avoid unnecessary x-ray exposure of the gonads of the patients, as long as medical diagnostic service is not impaired.

FIG. 46—A, X-ray therapy received 15 years previously for eczema of the hands, followed by development of squamous cell carcinoma which necessitated amputation.
B, Healed amputation stump, with the other hand showing ulceration which will probably progress to neoplastic change.

Ultraviolet Radiation.—Exposure to ultraviolet rays may cause a first degree burn, and if very extensive will result in shock and in some instances death. Extensive sunburn may be treated by bland ointments. Constant exposure to sunlight over a period of years, especially in blondes, may give rise to sailors' skin, a condition which resembles chronic radio-dermatitis and which not infrequently results in neoplastic changes in the skin.

Injuries Due to Cold

Donald R. Webster, M.D.

Introduction

While isolated cases of frostbite are relatively common in cold climates in civilian life, it is only in military campaigns that large numbers of cases are seen. This can be a matter of grave concern, and history records the bitter price paid by armies unprepared to meet the exigencies of winter warfare. The casualties

from cold injuries may far outnumber those from enemy action. There is often difficulty in providing adequate clothing and shelter and for evacuating the wounded. Many must remain immobile for long periods in cold and wet positions pinned down by enemy fire. At sea, survivors from sunken ships may sit for days or weeks huddled in lifeboats with their

limbs immersed in icy waters and their bodies exposed to winter weather. Besides the immediate loss of effective manpower, the victims of cold injuries may have sequelae that render them permanently unfit for service or incapacitate them for long periods.

Physiology and Pathology

The effect of cold on the tissues was described by Lake and most extensively studied by Lewis. Numerous workers since then have made substantial contributions. When an extremity is exposed to severe cold, vasoconstriction occurs, evidenced by blanching of the skin. This may be followed by a bright pink color due to vasodilatation and lack of dissociation of oxyhemoglobin. Vasoconstriction then occurs and is permanent in the chilled state. All of the vascular tree is involved, even to the major vessels. This appears to be a protective mechanism to conserve body heat, but it is at the expense of the exposed limb. The phenomenon of supercooling may prevent solidification until the temperature is considerably below that of the normal freezing point. As the temperature falls, the chilled or supercooled tissue becomes solidified, although brittleness is not evident in the ordinary clinical cases.

The damage to the tissue depends on the severity of the cold and the duration of exposure. There may be injury from anoxia due to the vasoconstriction and actual damage to the cells from the freezing process. The anoxic state is augmented by capillary stasis, especially as seen in chilled limbs without actual freezing where there is escape of the plasma, leaving the red blood cells in a state of "sitting" or "sludging," as described by Kreyberg and Greene. In frozen tissue considerable damage may be caused by the formation of ice crystals that continue to grow, disrupting the cells. This is not as evident in "quick freezing" as in a slower process. Experimentally, it has been shown that some tissues such as red blood cells may be frozen in glycerol and survive after thawing.

The thawing process is followed by a marked inflammatory reaction. Lewis suggested it resembled the "triple response" to histamine and thought the reaction might be due to the liberation of histamine like products from the

cellular injury. Thawing occurs either from without, in, or along the course of the vessels as circulation is re-established. Edema soon forms, with escape of plasma through the damaged capillary walls. This usually reaches its maximum in 48 hours. Stasis in the capillaries is apparently due to simple loss of plasma, possibly to the action of cold agglutinins or abnormal adhesiveness of the red blood cells. The surface temperature of the part is raised considerably, probably due to the opening of arteriovenous channels. These channels may rob the injured part of adequate circulation, as gangrene will sometimes develop in a part apparently well supplied with blood.

As edema increases, areas of cyanosis may appear, and there is always danger of infection in the devitalized areas.

There are many factors that modify the actual injury, such as the degree of cold, the duration of exposure, the surrounding medium, the resistance of the individual, and the effects of fatigue, emotion, and malnutrition.

Hypothermia*

Persons exposed to cold, who have had severe injuries, have been rendered unconscious, or are suffering from oligemic shock lose the protection of their heat-regulating mechanism, which results in a continuous fall of body temperature. This may be quite rapid in the range of 30-15° an hour in an adult and accelerated in children. The fall in body temperature is associated with increasing stupor, and when the low 80's are reached there is complete loss of consciousness. If the exposure continues, respiration becomes slower and shallow, the heart goes into ventricular fibrillation, and contractions finally cease.

In addition to the general hypothermia, exposure of an injured person to this environment will frequently result in frostbite of the limb or face. It may be difficult in some cases, because of the slow heartbeat and shallow respiration, to be certain that death has not occurred, and such persons should not be presumed dead until electrocardiographic evidence is available. Such errors have occasionally been reported in civilian and military practice.

*See Chapter 8 for the use of hypothermia in surgical operations.

Treatment.—Most cases of hypothermia will be of a mild variety and will respond to ordinary restorative measures. Severer cases must have the rectal temperature recorded by a special thermometer, blood pressure and respiration rate charted frequently, and if the pulse is difficult to obtain, the heart action should be followed by electrocardiography. The patient should be warmed by radiant heat and given oxygen. Positive pressure may be necessary. Care must be exercised not to interpret the signs of hypothermia as being due to hemorrhagic shock and the patient transfused unnecessarily, thus overloading the circulatory system. Respiratory depressant sedatives should be avoided. Electric defibrillation may be indicated if the facilities are available.

Emergency surgical procedure may be carried out if the temperature is over 80°, with minimal anesthesia.

Many terms, such as frostbite, immersion foot, trench foot, chilblains, have been used to describe the syndrome produced by exposure to cold.

Frostbite

Frostbite is the term used to describe the condition resulting from exposure to cold of sufficient severity and duration to produce apparent solidification in the affected parts. In frostbite there is vasoconstriction that can be relieved occasionally by vigorous rubbing as is often seen in the ears. This will frequently prevent further injury, as the resultant hyperemia will enable the tissues to maintain an adequate temperature. When the defenses are overcome, freezing occurs. Anesthesia is limited to the frozen area, thus differing from that found in immersion foot, and edema does not occur until the part is thawed. The sequence of events is then similar to that of injury due to chilling or wet cold.

Immersion Foot (Trench Foot, Water Bite, Lifeboat Leg, Seaboot Leg)

Immersion foot is the name given to a condition resulting from long exposure of the limbs in icy water or to a cold moist environment. The term is inadequate as the limb need not be immersed, and the condition also occurs in other members.

The severity of the cold is not sufficient to cause freezing, but the conduction of heat from the tissues sets up a syndrome that has immediate and disabling sequelae. It resembles and is probably identical with the trench foot of World War I. It occurs chiefly in survivors from shipwrecks who are forced to sit in lifeboats, rafts, or floats with their feet dangling in icy water. Cases have been reported occurring in warmer water, but these were associated with poor nutrition and long exposure to brilliant sunlight in cramped positions. After some hours of exposure, the feet, which are at first painful, become swollen and numb, the edema involving almost all the exposed part. They are first a livid color, which later changes to a pallid waxy appearance, and if the temperature rises slightly, they become mottled with blue and green areas. After rescue and exposure to room temperature the affected limbs pass through three stages: prehyperemia, hyperemia, and posthyperemia.

Prehyperemic Stage.—At first the feet are numb, the patient feels as though he were walking on blocks of wood, and he should always be assisted. The color begins to change from pallor to lividity, and the legs show various color patterns. Vesicles and even large bullae appear. There is anesthesia of a stocking type, with occasional hyperalgesic areas. The posterior tibial and dorsalis pedis arterial pulsations cannot be detected.

Hyperemic Stage.—At ordinary room temperature the feet quickly pass into the hyperemic stage. The limbs become hot to the touch and the color a livid red. The dorsalis pedis artery becomes palpable and bounding in character. The circulation is unstable. Congestion appears when the legs are in a dependent position and blanching when elevated. The pain at this period is intense and of a throbbing, burning character. This may last for several days and then change to a shooting, stabbing pain in the dorsum of the foot, radiating to the toes. This may last for several weeks. The edema increases, and large blisters are common, especially over the dorsum and malleoli. In severe cases, portions of the foot, usually the toes, remain discolored and cold, heralding the onset of gangrene.

Posthyperemic Stage.—The hyperemic stage soon merges in a few days into the posthyper-

emic stage. The burning shooting pains subside, but the feet are subject to intermittent aching pain, and edema readily appears when the feet are in a dependent position. The circulation is unstable, as evidenced by color

sist for a long time and present a difficult problem in rehabilitation.

Treatment of Frostbite and Immersion Foot.—The aim of the treatment of frostbite or immersion foot is to prevent or minimize

FIG. 17.—Appearance of feet of patient 2 days after suffering immersion for 24 hours

changes in different positions. Excess sweating common, and the patients complain of cold mny feet. Walking is often difficult as pro-
receptive sense appears deficient. The sensi-
ity to cold, hyperhidrosis, and pain may per-

necrosis. This has been the subject of a large
amount of experimental work and the interest
of many military surgeons. It was thought for
a long time that slow thawing or warming was
essential to allow the vessels time to recover

their tone and to limit the resulting hyperemia so that the increased metabolic demands of the injured tissues could be met by an adequate blood supply. To accomplish this, the limbs were rubbed with snow, packed in icebags, and cooled with fans or special cabinets. Experimental work in the last few years has indicated that less tissue is lost by rapid thawing than by slow warming and that stasis in the vessels is delayed. There is evidence that the larger vessels are in spasm during the chilling period and only relax when the tissue temperature is nearly that of body temperature. While the results of animal experiments cannot always be applied to man, it is probable that no harm is done by rapid rewarming of the frozen part to body temperature.

The blisters that have formed may be left intact, but if ruptured an occlusive dressing should be applied. Antibiotic drugs, antitetanic serum, and, when necessary, sedation for pain should be given. There is some evidence that anticoagulants may be useful in preventing thrombosis in the injured vessels, but they should only be used when adequate control is available. Vasodilating drugs, lumbar blockage, or lumbar sympathectomy has not been proved of value in the acute phase of frostbite nor in immersion foot where the sympathetic fibers seem to be inactive because of cold injury. They may be tried, however, if properly supervised, as an occasional case is apparently benefited by the procedure. However, in the late sequelae of painful, sweating hands or feet, where the digits become tapering and shiny and the movements restricted, sympathetic interruption is of considerable value. ACTH and cortisone have not been found useful.

Treatment must also be directed to keeping the injured parts scrupulously clean, to prevent any maceration between the toes and to protect them from infection and injury. Necrotic tissue should be carefully débrided, but amputation in the noninfected cases should be delayed as long as possible. It is surprising how often one may be deceived in mistaking superficial necrosis for gangrene of a large part. Following definitive treatment, physiotherapy is a most valuable aid to rehabilitation.

Chapter 7

Radioactive Isotopes in Diagnosis and Treatment

Carleton B. Peirce, MD, and Phoebe L. Cox, MD

INTRODUCTION

Disease of all or any part of the human body commonly is the result of some disturbance of the normal physiologic chemical processes or the physical state of the whole structure or one of its tissues. Heretofore, in the diagnosis of selected disease process, or the treatment of it, the physician has had to rely on what could be observed or determined from gross changes or end products by some means which has stopped the abnormal chemical reaction, altered the physical aberration, or diverted the irregular or abnormal physiologic process back into normal channels.

If any one of the several chemical elements and their compounds used throughout the body, or in a given tissue, can be labelled or "tagged," perhaps to microchemical levels, the true normal or abnormal physiologic process might become known. The discovery of the phenomenon of natural radioactivity and its sequel, the production of radioactive isotopes, has provided the tools.

Curiously, near the end of the last century (1873), almost simultaneously Becquerel discovered that pitchblende gave off some sort of penetrating "rays" and Roentgen found that γ could induce a similar radiation by projecting an electric charge against a relatively hard or dense metal target. Not long after, Pierre and Marie Curie isolated radium (one

of the "natural" radioactive elements) from the pitchblende ore, demonstrating that this element was the source of Becquerel's rays.

The more than 60 subsequent years have seen, almost tumbling one on top of the other, verification of Dalton's hypothesis of the structure of matter and its component chemical elements; Rutherford's identification (at McGill, 1904) of the alpha particle (α) by using atomic bombardment; his further studies here and in the Cavendish Laboratory at Cambridge, which were a foundation for Bohr's atomic theory (1912), Rutherford's proof of the existence of the proton (p) in atomic nuclear structure (1919); demonstration of the neutron (n) by his successor, Chadwick (1932). Experimental evidence has amply supported these broad principles which underlie the development of present-day knowledge of atomic and nuclear structure and radioactivity.

Further exploration of theoretic and applied physics, aided by the invention of the cyclotron (Lawrence, 1932), the discovery of artificial radioactivity (Curie and Joliot, 1934), and, during World War II, the concentration of knowledge, research, and effort on atomic energy, resulted in the control of "chain reactions" to split atoms into various pieces. The development of the nuclear reactor ("atomic pile") has made possible production of many "artificial" radioactive isotopes in usable quantity and in a variety which had been anticipated

For example, in the early work on the rate of entry of potassium from plasma into rabbit red blood cells, Hahn et al. (1939) bombarded a target of KCl with deuterons in a cyclotron. With the extracted K^{42} , an exchange rate of only 3% was determined. Mullins et al. (1941) later repeated this work and obtained a 50% exchange. In the preparation of their material, the cyclotron-produced radiopotassium was chemically purified further so as to remove the 0.02% NaCl present as a contaminant of the KCl target material. In the earlier work, the chemically insignificant sodium, when rendered radioactive (Na^{24}) in the cyclotron, had been a physical contaminant whose discharges were not distinguished by the instrument. Hence, as determined from counting its nuclear or physical discharges, there appeared to be an erroneously high concentration of isotope as predominantly an extracellular ion in the plasma.

Another type of radiochemical impurity may be due to either a different valence state or a chemical combination of the desired isotope other than the one believed to be present. For example, in the preparation of $P^{32}O_4$ by neutron bombardment of $K_2HP^{31}O_4$, a variable fraction of the P^{32} so produced (for a still unknown reason) assumes some form other than the orthophosphate. This was first brought to light in the observation that recoveries of P^{32} from such material (used as a tracer) were impossibly high in comparison to the amount of radioactivity present in aliquots of the original material precipitated as the orthophosphate of $MgNH_4PO_4$. Jacob Sacks suggests that the energy liberated in the nuclear reactions forming the P^{32} from P^{31} is sufficient to break chemical bonds, thus leading to a chemical form different from that of the target material. (A similar change may happen as a result of ionization in tissues subjected to radiation of any kind and may account for the considerable latent effects of apparently insignificant radiation.)

A third type of radiochemical impurity is the presence of two or more radioisotopes of the same element in a given preparation. For example, in the bombardment of tellurium with deuterons in the cyclotron, both Te^{130} and Te^{131} are formed. The former has a half life of 12 hours, the latter one of 8 days; both emit

negative beta particles and gamma rays. After a short bombardment period, the relative radioactivity of the Te^{130} is about 10 times that of the Te^{131} . Such a combination of isotopes of the same element can lead to results that would be difficult to interpret.

Exchange.—Another phenomenon which may cause trouble in certain types of isotope tracer investigations is exchange, especially in determination of rates of synthesis of a given compound. For example, if one wishes to study the rate of deposition of new phosphate crystals in bone, replacement of the $P^{31}O_4$ of previously deposited crystals by exchange with recently administered $P^{32}O_4$ will give an erroneously high value for neoformation of such crystals.

Similarly, it has been found that use of radioactive water (HTO) to determine by dilution the amount of body water is fraught with an inherent error due to exchange of the tritium for the H of the OH radical of carbohydrates and of peptide bonds on proteins.

Determination of Quantity of Isotope Required for Diagnostic Purposes.—A second special and practical consideration in tracer studies is the actual quantity of an isotope to be administered. Since counting apparatuses can detect the amount of isotope present in a given place in a given time, only dependent upon the character and frequency of its emitted radiation, a sufficient number of atoms must be administered to obtain a substantial count over the desired location with the apparatus available within a time period which will tire neither the patient nor the investigator. This limits the minimum amount of the isotope to be given.

The maximum quantity should not exceed the number of atoms which may be tolerated without disturbance of the normal dynamics of the element or substance under study. Two factors affect this amount—the half-life of the isotope and the amount of "carrier" (the nonradioactive isotope of the element present in the sample of radioactive isotope to be used).

I^{131} and P^{32} exemplify these two characteristics. I^{131} has a physical half-life (disintegration of 50% of the atoms present) of 8 days. Therefore, in a given location in any given period of time, such as 100 seconds—in order to have a "count" of 100 (disintegration of

100 atoms)---actually there have to be 100×10^3 atoms of the isotope present. P^{32} has a half-life of 14.3 days (a slower rate of decay). Therefore, to have the same count with P^{32} , there would have to be present 178×10^3 atoms. In both cases, the amount required will depend also upon the apparatus, which will be able to respond to only a fraction (usually known) of the total number of atoms decaying at any one moment.

Lest the reader be staggered by the magnitude of these figures, it must be remembered that one microgram of I^{127} contains 4.75×10^{15} atoms, a similar amount of P^{32} contains 1.89×10^{15} atoms. Furthermore, the presumed normal daily dietary of stable iodine (I^{127}) is of the order of 100 μg , and that of stable phosphorus (P^{31}) is probably measurable in grams rather than in micrograms.

Since I^{131} is produced by slow neutron bombardment of tellurium¹³⁰ and decays to xenon,

it is available as "carrier-free" isotope. That is, no I^{127} should be present in the material used for tracer study.

P^{32} , on the other hand, is usually prepared by the bombardment of S^{32} with neutrons, by proton emission becomes P^{32} , and that in turn decays to S^{32} .

In the extraction of the phosphorus isotope from the sulfur, large loss of the P^{32} is inhibited by the addition of chemically small amounts of P^{31} . As a result, stable isotope is mixed with the radioactive one, so that the latter is not "carrier-free," and the administration of the P^{32} usually will include a chemically small but numerically large quantity of P^{31} atoms.

Other Factors in Selection of Tracer Substance.—If a substance is made up containing an isotope whose radioactivity is to be used to detect, "tag," or "label" the normal behavior of that substance in the body, the isotope must be so incorporated into the

molecule that it will not be exchanged or broken off in the normal metabolic use of that compound.

For example, P^{32} in a phosphate group attached to a given substance by an ester linkage is a most unsatisfactory label, because such an ester linkage is unstable. As a result, the $P^{32}O_4$ radical rapidly parts company with its parent substance. On the other hand, I^{131} incorporated into a tyrosyl radical is a satisfactory tag, because the bond between the iodine and carbon is as strong as the carbon to carbon bonds of the tyrosyl radical. Loss of the iodine from such a radical would be equivalent, therefore, to disruption of the ring, hence degradation of the compound concerned.

Another example of a good label for a complete molecule is the linkage of radioactive hydrogen, tritium (T), to carbon in place of the hydrogen in the C-H bond, for this is strong, and the tritium will stay with that particular carbon atom under most circumstances. But linkage of tritium to oxygen, as in an OH radical, is an unsatisfactory tag, due to exchangeability of the H as already pointed out, a situation similar to the P^{32} of a PO_4 radical in ester linkage.

It is evident then that, if an isotope is to be used as a label for a complex molecule which is to be traced, the isotope selected must be incorporated into the molecule under study so as not to be separated easily from the labelled molecule.

Character of Tracer Investigations.—The applicability of radioactive isotopes to diagnostic problems will be determined by the type of problem to be studied.

Whether or not capillary and fixed tissue cell membranes of traumatized areas have become more permeable and, if so, to what substances; the mode of synthesis of the hemoglobin and the duration of red cell life; and the extent of the extracellular space in congestive heart failure and nephrosis can be elucidated by use of isotopes.

Determinations of circulation time and, in some degree, distribution to the lower limb as an aid to when and where to amputate in cases of circulatory disorders, studies of thyroid function, of plasma and red cell volume, and of detection of malignant lesions

comprise the majority of diagnostic tracer studies at present.

It must be remembered that if one desires to investigate an abnormal situation, some concept of the normal must be established. Hence, insofar as possible, comparison must be made with a sufficient number of presumably normal individuals whose biologic and environmental conditions have been and, during the period of study, remain equivalent to those of persons who appear to be abnormal.

Physiologic and disease processes may be grouped as follows, dependent upon the type of chemical substance which may be most useful as an analytic label:

1. Distribution and disposition of body fluids and electrolytes, or utilization of specific simple ions, such as Na^+ , K^+ , or Cl^-

2. Similarly with simple or specific radicals, such as PO_4^{3-} or I^-

3. Intermediate metabolism of biologically important organic compounds or specific cellular elements, in which readily traceable elements such as iodine and phosphorus are normal components or may be used as labels

4. Synthesis, distribution, and metabolism of specific compounds such as hemoglobin or serum albumin

5. Aberrations in physiologic synthesis or normal breakdown of biologically important compounds such as thyroxine

6. Location, extent, and physiologic activity of specific organs, tissues, or masses with selective avidity for a traceable element, such as the thyroid gland, halide-secreting cells, or neoplasms

Diagnostically at present, the isotopes in appreciable use are limited to Na^{24} , P^{32} , I^{131} , and Cr^{51} . Ca^{45} , Sr^{90} and Sr^{90} , Fe^{59} and Fe^{59} , and K^{42} have been used more in pure investigation. Considerable evidence is accumulating as to an osteosarcomagenic hazard from strontium²²

The life span of red blood cells in various blood dyscrasias is currently under investigation by means of labelling the cell with one of the isotopes of chromium (Cr^{51}) and then determining the rate of removal from the circulation.

The extent of a traumatized area could be determined by use of Na^{24} . But that is a short-lived isotope (half life 14.8 hours); hence, a

careful clinical assessment is certainly simpler and presumably sufficiently precise.

The extent of increase of the extracellular space in congestive failure and nephrosis can be obtained fully as precisely by use of thiocyanate as with Na^{24} ; and, what is more, its decrease can then be followed quite satisfactorily by the simple expedient of daily weighing, provided, of course, that the scales used register 10 pounds as 10 pounds, day after day.

There are problems to which isotopes can give exact answers; but in many of these, answers adequately good for clinical practice can be obtained by far simpler means. This does not disparage at all those investigations which are in progress to determine more precisely the actual physiologic pattern—about so much of which so little is known.

Radioactive Sodium (Na^{24}).—The short half-life of this isotope precludes its clinical use, to any major extent, save when the investigation can be done close to the source of production.

Shortly after artificial radioactive isotopes were first produced (1934), some quite spectacular demonstrations of their presence were in vogue. One of these was the detection, with a Geiger-Müller counter and annunciator, of gamma rays in the finger tips of a person who had just imbibed a cocktail of Na^{24}Cl .

Smith and Quimby (1947) put the prestidigitator's technique to respectable diagnostic use by comparing the rate of isotope count increase (following intravenous injection of a known amount of Na^{24} into the antecubital vein) over the affected limbs of patients with peripheral vascular disease to that of normal individuals. In their hands, the build-up over the sole of the foot of the normal person reached a plateau in about half an hour, whereas in those affected with vascular impairment the plateau was attained after a considerably longer period. The rate of build-up could be interpreted also in terms of adequacy of the circulation in the involved extremity. Although elaborate technical procedures were necessary, the results justified the effort, for by this means certain patients with thromboangiitis obliterans, or telenosclerosis with diabetes, or chronic ulceration of the leg, which by ordinary clinical judgment would have been subjected to a high am-

The radioactive iodine diffuses uniformly through this so-called "iodide pool" of plasma and extracellular fluids, mixing with whatever ions of stable I^{127} happen to be present at the time. As a result the body's whole population of iodide becomes uniformly labelled. That is, if there were 1,000 ions of I^{127} and 10 ions of I^{131} (once mixing is complete), for every ion of I^{131} in any locus there will be 100 ions of I^{127} . This dilution or uniform diffusion is important, because the rates at which both the thyroid and the kidney will remove I^{131} from the circulation will depend upon the inherent avidity of these two organs for all iodide ions and the number of such ions available to them in any given volume of blood, hence in the extracellular fluid bathing their respective cells at any given time.

In congestive failure, the radioactive isotope, with its fellow stable iodide and chloride ions, may become sequestered in these extracellular fluid spaces for some time. This is of importance in the differentiation of cardiovascular disease complicated by abnormal thyroid function. The spleen, in its capacity as a blood reservoir, can sequester the isotope also, thereby upsetting expected physiologic time relationships.

When such sequestering aberration is present, a peripheral tissue area such as the thigh is relatively slow in reaching its normal peak concentration and considerably slower than normal in showing clearance of the isotope from the general "iodide pool." In fact, a persistently elevated peripheral tissue count may be used as a sensitive index of otherwise unrecognizable occult edema.

Shortly after oral administration, when the plasma still has a relatively high radio-iodide content, the count observable over the submaxillary and sublingual glands erroneously can be thought due to aberrant thyroid tissue or malignant thyroid cells in cervical lymph nodes.

Whenever food is ingested after the isotope has left the stomach initially, a rise in count over the stomach indicates that this organ is using the iodide ion in the same way it uses a chloride ion in elaborating acid gastric juice. The stomach, as well as the salivary glands, may contain concentrations of iodide ion some 30 times that in the blood circulating through

them at a given time. The iodide ions secreted into either the saliva or the gastric juices will reach the small intestine again, where they rejoin or repeat the cycle. Furthermore, after the first 24 hours following ingestion of the radioactive iodide, the degree of rise in count over the stomach postprandially can be used also as an indication of the amount of isotope still present or newly entering the circulation.

The Metabolism of Iodine Within the Thyroid Gland.—Iodine is taken up by the thyroid gland as the iodide ion, in which form it finds its way from the extracellular fluid about the capillary, by which it was brought as a constituent of plasma, to the parenchyma of the gland, across the cell membrane of the thyroid follicle cells, and subsequently rapidly distributed throughout both cellular and colloid elements of the follicle.

As yet there is no completely satisfactory explanation of the specific mechanism by which iodine is concentrated in a thyroid follicle. All that can be said categorically is that this mechanism is highly efficient, for the gland can extract iodide ions from plasma even when the ratio of the concentration of iodine in the gland to that in the plasma is 1,000:1. This does not mean that the concentration of iodide ions is great within any gland follicle. In fact, it is probably small, and some ions may diffuse almost immediately to the circulation. Probably, the remainder are oxidized to a form capable of reacting with tyrosyl radicals and thus form first mono-, and, second, di-iodo-tyrosyl. The latter two iodine-containing radicals are constituent parts of the large protein molecule thyroglobulin.

The precise locus of this iodination, the necessary chemical conditions for which must exist within each follicle, is at present controversial. However, the possibilities seem to have been reduced to a hollow sphere whose perpendicular wall thickness, occupying the cell-colloid junction, is less than 1 μ .

Once the iodide is thus joined or incorporated into the tyrosyl radical, spatial relationships allow such radicals to condense, with elimination of the alanine fraction of one, and thereby to give rise to thyroglobulin side chains of thyroxine or tri-iodothyronine, still bound by peptide linkage to the parent molecule in the colloid. These linkages are severed

enzymatically along with those of uncoupled mono- and di-iodotyrosine from the parent protein. As free amino acids they are capable of diffusing from the colloid into the circulation. However, a dehalogenase within the thyroid cell itself attacks the tyrosine, but not the thyronine amino acids as they diffuse through, and removes the attached iodine which, in turn, is free either to diffuse out of the follicle as iodide ion or to be reinvolved in the iodination of similar radicals attached to other thyroglobulin molecules.

Newly formed iodinated tyrosyl radicals, newly formed iodinated thyroglobulin molecules, and newly proteolyzed thyronine derivatives in turn undergo uniform distribution in the iodide pool within the gland. It is assumed (there being no evidence against it) that any iodide entering the thyroid at any given moment is subjected immediately to random distribution in the intraglandular pool, and that subsequent newly entering ions will behave similarly. Presumably, the newness of entry in no way makes any one unit different from similar units which may have been present in a given pool for varying lengths of time. It is this fundamental assumption of the randomness of distribution which has allowed the clarification of these steps by application of the philosophy of precursor-product relationships (Zilversmit et al., 1943) within this gland. This assumption permits an explanation of the early appearance in the circulation of labelled hormone from a gland already practically bursting with previously stored hormone.

On ingestion of a tracer dose of I^{131} , these iodide-organic-iodine transformations within the gland take place between the initial uptake and the reappearance of I^{131} in the periphery. The individual steps are indistinguishable at present, for only the number and energy of the I^{131} atom disintegrations are measurable. This decay of the isotope is independent of any chemical process or other influence, save the necessity in each atom to sooner or later achieve physical balance by expulsion of its excess nuclear particle beyond the restraining short-distance-acting intra-atomic forces.

What can be determined is the minimum time required for the complete sequence of changes between entry of a tagged iodide ion and the release of similarly labelled thyroid

hormone into the circulation. Subsequent to this release, the amino acid, apparently loosely bound to an albumin fraction of the plasma proteins, is carried via the systemic circulation to the peripheral extracellular fluids whence it may become intracellular and effect its specific hormonal action.

The question of whether thyroxine or tri-iodothyronine, in actual fact, is the effective tissue hormone remains unanswered.* Certainly the mechanism of fixed-cell membrane penetration is unknown, to say nothing of the nature or control of its definite intracellular role. Elucidation of the latter should provide ultimately some clue to the riddle of the various thyroid states—perhaps the answer to the WHY of Graves' disease.

Therefore, in the still very limited knowledge of thyroid disorders, I^{131} tracer studies can at best provide, in any one case, definite answers to only certain specific questions, if the iodide ion has free access to the extracellular fluid between thyroid capillaries and thyroid follicles, namely:

1. What is the size, shape, and location of the thyroid gland?
2. Is the distribution general or of nodular hyperactivity, or of definite lack of iodine uptake as in malignant disease?
3. Are there other masses of iodine accumulating tissue present in the body? If so, where and how large are they? (Other than the thyroid, the polysaccharide capsule of the tubercle bacillus is the only iodine-concentrating material currently known. Intrathoracic cold abscesses have caused confusion.)
4. What proportion of iodide is taken up by the gland and in what interval of time? Does this fall within the range previously determined as normal for the given environment?
5. If not, how great is the "avidity" of this gland for iodide ion?

The thyroid gland in a normal "steady state" has a certain constant or normal requirement of iodine to maintain its hormone fabrication and reserve. This will be approximately 100 mg. of iodine per day for an adult.

It is probable that with deficiency of iodide supply the individual's fabrication of hormone will be altered.

*Thibault and Pitt Rivers (Lancet, 1935) have shown that in vitro the acetic acid analogues of thyroxine and tri-iodothyronine immediately cause a rise in the oxygen consumption of rat kidney slices and suggest that these are the tissue active forms of the thyroid hormones.

Further, if the thyroid-stimulating factor of the pituitary whips the thyroid into greater activity or some other alteration of the metabolism, so far as undetermined, causes increased demand surpassing ordinary requirement as in thyrotoxicosis, the relative greed for iodide may be spoken of as "avidity."

6 How rapidly is the iodide ion being transformed into thyroid hormone? (This can be observed by continuing iodide entry.)

7 At what rate is hormone being released? This may require observation over a period of several days.

Technique of the I^{131} Tracer Study of Thyroid Function.—The method or technique adopted for an I^{131} tracer study should be such as to answer best all or the majority of the questions posed above with the smallest practicable amount of radioactive isotope, the best economy of time and effort on the part of the patient and the examiner, and the least amount of physiologic disturbance of the patient.

Some observers have devised various short cuts or have selected certain periods for observation from which they extrapolate "uptake" and "excretion" curves and by which they achieve an interpretive assessment. Such techniques are not as trustworthy as desired in cases other than those which are relatively obvious clinically.

In our opinion, a more detailed series of observations should be employed regularly in order adequately to assess the situation and particularly to analyze the more obscure considerations of masked thyroid dysfunction, such as those in association with cardiovascular disease and diabetes.

The following technique is preferred

- 1 A dose of 50 μ c of I^{131} as NaI in 3-8 oz of water is given by mouth after an overnight fast and before breakfast. A normal breakfast should follow in 1/2-1 hour. Pleasant surroundings are provided so that the patient is as much at ease as practicable, and the findings will be physiologic.
- 2 Beginning 2 hours later, counts are taken of the thigh, liver region, chest, and neck, with an opposing pair of Geiger tubes mounted 50 cm apart on an adjustable carriage.

- 3 Detailed local scanning and counts of selected points, with an end window Geiger-Müller tube, sensitive to beta particles as well as to gamma rays, is done routinely over the thigh, liver, epigastrium, splenic area, upper end of the sternum, manubrium, sternal notch, and at least 3 points over the thyroid at similar periods preferably at 2, 3, 8, (12), 21, and 36 hours after ingestion of the isotope.

4 Each voided urine specimen is assayed with a liquid counter for I^{131} excretion up to 32 hours.

5 Curves (corrected for physical decay) of the thyroid isotope uptake and of the cumulative periodic urinary discard, expressed as per cent of administered dose, are constructed from these data.

6 Iso-topographic drawings of the detailed neck-scanning, preferably to scale on a tracing of the patient, are readily made and very useful.

7 In the assessment of each patient, these collected data are used to check stomach emptying, patency of vascular beds, sequestration of the isotope in spleen and extracellular fluids, secondary concentration of hormonal isotope in the liver for detoxification of excess thyroxine and clearance from the blood.

Counts over the upper end of the body of the sternum indicate the concentration of the isotope within the great vessels of the middle mediastinum, while those over the lower half of the manubrium will assay, in large measure, the amount in the blood flowing through the aortic arch.

Gland counts should include at least those perpendicular to the center and long axis of the isthmus and of each lobe of the thyroid, and at angles of 45 and 90 degrees medially and laterally. Assessment of the activity, size, and position of the isthmus and each lobe must be accomplished, or the observer is not doing his job properly.

Measuring instruments must be initially and repeatedly calibrated against known amounts of isotope, preferably with an anatomically correct plastic model.

In each geographic area and for any peculiarly segregated environmental group, the normal average uptake and "range of normal" must be determined by tracers on presumably normal volunteers (interns, medical students, and patients ill with other than thyroid disorders) in whom there is no recognizable or even suspected thyroid element, all being endogenous to the area and environmental conditions.

In assessment of the state of the thyroid in any one patient, a careful history, the BMR, and blood cholesterol levels as well as other laboratory tests, such as ECG's and blood sugar studies, are indicated. Total and protein bound blood iodine determinations are valuable in certain borderline cases. Normally, free blood iodide equals about 0.3 μ g %. an amount too small to measure accurately in ordinary samples of plasma.

The particular times chosen for counting are recommended for the following reasons:

Absorption, thorough mixing, and uniform distribution throughout the iodide pool is not completed in less than 2 hours after ingestion of the NaI^{131} test dose. If, at that interval, a high count over the epigastrium indicates possible pylorospasm, simple reassurance will ordinarily induce relaxation, detectable as a sudden spurt in the counting rate over the duodenum.

Zero time, the time of administration, can be

advanced then to this observation moment. Normally, the 2-hour observations will indicate the degree of avidity of the gland for iodide, the proportionate dilution is rarely known. At that period also, the plasma has a relatively high radioiodine content. The observer may find an increased count over the submaxillary and sublingual glands. As comparative data, later observations will correct possible error in suspicion that such may be due to aberrant thyroid tissue or malignant thyroid cells in the cervical nodes.

The 5-hour count period falls just after lunch—a convenient time to check on the efficiency of the body's use of iodide as a halide. The epigastric or stomach count should be elevated, salivary gland count down, peripheral tissue counts falling. Thyroid counts should provide evidence as to whether or not the thyroid is capable of holding onto the iodine it has collected or is concentrating.

In cases of acute thyroiditis, either cell-membrane permeability or the ability to collect and use iodide, or both are affected. In this condition, at 2 hours after ingestion, when the plasma level of iodide ion is high, the thyroid level is comparably high. Thereafter, as the plasma iodide ion count falls, so does that of the thyroid. Splenic concentration of isotope should be assessed at this time and later. If blood without or with the isotope is stored in the spleen, its release subsequently would either suddenly dilute or increase the concentration of isotope in the circulating plasma and hence affect the count in all the peripheral fixed-tissue areas.

The 8-hour observation, before supper on the first day, affords comparison or confirmation of the trends suggested at the two earlier periods. The third set of periodic data in this first day permits curve constructions which give a truer sense of the tissue-isotope behavior. In really toxic hyperthyroid patients, the peak uptake is reached by the gland early, often by 6 hours. An 8-hour count will show whether the uptake is still rising, is constant, or has started to fall (a possible indication of rate of fabrication of iodide ion into circulating thyroid hormone).

By 24 hours, for normal patients, there has been a sufficient time lapse for the extrathyroidal tissues to have been cleared and for the

thyroid to have reached its peak concentration. However, this is not always true, for even at 32 hours or later, the thyroid concentration ("count") may be continuing to rise and the peripheral count to fall in some presumably normal individuals. This is common especially in patients with sluggish circulation (Twenty-four hours is a check point chosen by some laboratories using a short-form tracer study. However, it must be remembered that a single measurement at a single time provides only meager information on how a complex organism may be handling a single element, and definitely indicates only the status at that particular moment).

In the majority of patients, by 32 hours the periphery is free of isotope, or nearly so, and the gland is well filled with it. This is the time at which a definite concept can be formed of the size, shape, position, and intimate reaction of the gland to this element.

For some patients, especially those with cardiac disease, the tracer observations have to be continued into a third or even later day before the periphery will have cleared sufficiently.

Observations can be extended until sufficient data are available to assess the rate of hormone release from the gland, although this is complicated by re-use of isotope released by hormone degradation in peripheral cells. One is likely to forget that only the raw material for hormone synthesis, the iodide ion, has been provided. In no way can impatience for an answer and possible resultant diagnosis speed up the orderly time sequences of nature's processes. Furthermore, the time clocks in various human beings are not synchronized, and in each individual the rate may change from time to time, due to varying conditions. With increasing experience, determination of certain specific check points may be practicable. Albeit, in problem cases, for whose diagnosis a careful tracer study is of the greatest usefulness, it has been repeatedly evident that the most detailed examination is the most economic in the achievement of a positive diagnosis.

Tracer Use of I^{131} Attached to Organic Molecules.—

Radioiodinated serum albumin (R.I.S.A.)
Since radioiodine can be chemically added to

RADIOACTIVE ISOTOPES

the tyrosyl radicals of the long chain organic molecules, such as serum albumin, without altering their biologic activity or immunologic properties, such preparations can be used to label and hence trace the physiologic behavior of similar nonradioactive molecules in the body.

Plasma volume can be determined with radioactive iodinated human serum albumin (in known quantity) injected into the blood stream, and its dilution by the solvent (blood plasma) volume assayed (measured in terms of radioactivity per unit volume).

Thorough intravascular mixture of added serum albumin is completed in 10-15 minutes. By that time none of the newly added albumin will have left the vascular tree. However, by 1 hour 10%, by 5 hours 20%, and by 24 hours 45% of the added RISA will have left the circulation to become equilibrated with the total body albumin occupying the "albumin pool" which presumably corresponds to the extracellular body water—some 15% of the total body weight. In 1 hour, some of the intravenously injected RISA has been reported to have appeared in lymph obtained from the thoracic duct.

Calculation of plasma volume is of particular value in anemia, in cases for replacement of blood loss—operative or essentially hemorrhagic—and preoperatively in the chronically ill patient with a probably contracted blood volume.

RISA has certain advantages over the dyes used in the older and classic dilution methods previously employed, in that:

- 1 The material is a normal physiologic component of plasma.
- 2 The small amount required will not upset the normal dynamics of the albumin already present.
- 3 That amount (5 ml of a suitable dilution of a commercially prepared sterile RISA) is sufficiently radioactive (10-15 μ c of 131 I) that its diluted fraction can be detected and measured in a small sample of blood drawn from the antecubital vein 10-15 minutes after injection of the original tracer quantity into the opposite antecubital vein.

After noting and recording the hematocrit reading, the sample is centrifuged, and a 1 ml portion of the resultant plasma measured as to its radioactivity in a well type counter. Comparison with the radioactivity of a standard dilution of the original injection material (1 ml. of a 1,000 ml dilution of an equivalent

volume of the injection solution) permits ready calculation of that particular patient's plasma and total blood volume.

Correction factors will include the following:

- 1 Plasma trapped between red blood cells—considered equivalent to 4% of the height of the column of packed red blood cells in the hematocrit reading.
- 2 The venous hematocrit correction, known to be 10% higher than the total body hematocrit.

Together these give a combined correction factor of 0.87.

Furthermore, such plasma volume determinations, especially if coupled with concurrent calculation of red cell volume, are valuable in selection of the proper replacement or substitution medium—whole blood, plasma, or packed red cells.

The progress of substitution therapy, undertaken as a result of the first determination, may be closely checked by withdrawal of a similar blood sample, determination of its contained radioactivity, and then injection of a second test volume of R.I.S.A. with similar assay of its dilution corrected by the known residual activity in the second pre-injection sample.

Localization of malignant tumors in brain or liver has become possible with radioiodinated serum albumin. If the blood-brain barrier deters entry of small molecules to the cerebrospinal fluid—the true extracellular fluid of nervous tissue—and the brain tumor is nourished from the extracellular fluid, which diffuses out of the involved blood vessels directly supplying the mass, there may be a relatively specific detention of the radioactive albumin in the tumor, the isotopic nuclear decay of which may then be detected as in other external tracer studies (Radioarsenic [75 As]) may be used with a scintillation counter but is not commonly employed.)

The situation regarding metastases to the liver is less easily explained, there being no such barrier on which to call. Philosophically, there may be increased, slowly turning over extracellular fluid—in effect, an edematous response to the abnormal growth—or the serum albumin may be the precursor for the protein portion of the nucleoprotein which is being rapidly synthesized in such tumor masses.

Whatever the reason, the fact remains that given a sufficiently large mass, sufficiently different from its surrounding normal tissue, such a mass can be detected in either location by the difference in radioactivity count rate of the normal compared to the abnormal tissue. The time interval chosen for such determination should be sufficiently long after intravenous injection of RISA to allow thorough equilibration with the extracellular fluids but before the iodinated albumin has begun to be destroyed by normal metabolic processes. This would suggest not less than 2 hours and not more than 24 hours. Sensitive instruments and discriminatory survey of the area are required.

Chromium⁵¹ in Determination of Red Cell Volume and Survival.—Red blood cell volume determinations with Cr⁵¹ are done in a manner somewhat similar to that employed for plasma volume determinations with radioiodinated serum albumin, except that the patient's own red cells must be taken, processed, and reinjected.

If these red blood cells are incubated with sodium chromate ($\text{Na}_2\text{Cr}^{51}\text{O}_4$) which has been made radioactive in an atomic pile, 97% of the Cr⁵¹ taken up will bind strongly to the contained hemoglobin, while the remaining 3% is attached to the stroma. (Of 50 μc of Cr⁵¹ in the incubation mixture, 50-90% will be incorporated.) The incubated, now radioactive, red blood cells must be washed free of the residual unincorporated Cr⁵¹, avoiding, insofar as possible, lysis of the cells.

When survival studies are to be done, injury to the red blood cells must be avoided. For that purpose and to reduce the hazard of washing the red blood cells, ascorbic acid is added to the incubation mixture, in order to convert the trivalent reactive Cr⁵¹ into the unreactive hexavalent ion, which is rapidly removed upon injection into the circulation. This method has the possible advantage of using the patient's own red cells as the labelling agent but requires rather meticulous processing of the cells under aseptic conditions and their reinjection, followed by the third venipuncture for the dilution sample in the volumetric study.

In the survival studies, samples are drawn every second day after injection of the tagged cells, until a satisfactory curve can be constructed of the rate at which these cells are

leaving the circulation, presumably either by hemolysis or splenic destruction. The curves constructed are not corrected for either physical decay of the isotope or for the slow elution of the chromium from the cells themselves, which occurs at the rate of 1% / day. This latter factor is also affected by the age of the cell and seems to increase with age. Rather crude or uncorrected curves result. To obtain absolute survival rates, incorporation of one of the radioactive isotopes of iron into newly synthesized hemoglobin would be preferred, but the isotopes of iron (Fe^{55} and Fe^{59}) are difficult to use due to their half-lives (respectively, of 4 years and of 47 days) and also due to the character of their disintegrations, namely, by K capture (Fe^{55}) and by emission of soft, hard-to-detect beta particles, and hard and also poorly detectable gamma rays (Fe^{59}).

Nonetheless, comparative studies of survival rates in the different kinds of anemia may in time shed much light on such questions as whether a particular anemia is due to failure of formation, increased fragility, or excessive destruction of the particular red blood cells, or to some combination of these factors.

Radioactive Phosphorus (P^{32}).— P^{32} can be produced in the cyclotron by deuteron bombardment of P^{31} plus proton emission, or in the atomic pile by slow neutron bombardment of S^{32} plus proton emission. As mentioned before, it is not obtainable "carrier-free." The energy spectrum of its emergent beta particles is fairly broad, with an average of 0.695 mev (million electron volts). At most, these beta particles can travel 0.8 cm, and on the average only 0.27 cm through tissue. In transit, they may produce *bremsstrahlung*, a type of secondary electromagnetic radiation (like x-rays). The probability of their doing so is 1,000:1. The *bremsstrahlung* have an energy spectrum similar to that of the emitted beta particles, and like the beta particles lose momentum as they pass through matter. The geometry of the end-window Geiger-Müller tube used for their detection, i.e., the portion of total detectable rays actually "seen" by a given instrument, is at best only 50% and usually considerably less. Such a counter is responsive to about 1% of the *bremsstrahlung* that actually passes through it. When all these factors are taken into account, detection of P^{32} concentrations any dis-

tance below the surface of the skin in tracer studies *in vivo* is physically difficult.

In man, phosphorus may be considered as a universal cell constituent, for it is involved in intermediary metabolism reactions. Since there is so much of it normally present, and since the body cannot distinguish between P^{31} and P^{32} , the body tissues and individual cells will use either one indiscriminately. Administration of a chemically small amount of P^{32} along with P^{31} affects the various phosphorus pools less than a similar amount of stable isotope would affect those of P^{31} , a larger surely and easily detectable as P^{31} , a larger dose would be required to get numerically comparable counts, because P^{32} has a longer half-life (14.3 days). It is, however, easily producible, transportable, and a physiologic element.

Much study has been devoted to the chemistry of phosphorus and its compounds, especially the phosphate, the form it so commonly takes within the human body. This radical (PO_4), stable enough within itself, splits from compound to compound, thereby transferring the necessary energy for anabolic and catabolic processes. Phosphate is involved in carbohydrate, fat, and protein metabolism, in the creation of new nucleoprotein required for cell division, in the chemistry underlying muscular contraction, in the solidification of the skeleton by deposition of calcium phosphate, as well as many other physiologic processes. Attention has already been called to the problem of exchange in bone crystals. This extends to other phosphate ions as in the circulating fluids. In intermediary metabolism it is joined to one complex after another by ester linkage, and in the elaboration of new nucleoprotein all of the phosphate of any given nucleus is wholly replaced each time a cell divides. Even its absorption from the gastrointestinal tract, as well as its transport across tissue cell membranes, is dependent upon an active process that involves linkage of it to something else—probably glucose or one of its derivatives.

Theoretically, phosphorus should be concentrated wherever cells are dividing, and undoubtedly it is, but there are so many places in the body where cells are normally dividing all the time. To recognize special regions, such as malignant tumors that are rapidly growing,

requires that the obscuring background of all the other processes be allowed to run their course and exchange back to the circulation the $P^{32}O_4$ for new $P^{31}O_4$, taking the place of the now excreted $P^{32}O_4$. Since such tumor cells are dividing at a greater than normal rate, they should lose the concentrated phosphorus more rapidly than do the normal sites, because all, not just part, of the phosphorus is renewed during division.

If P^{32} is to be used as a "tracer" for detection of malignant lesions, it is necessary that the suspected lesions be close to the surface, that sufficiently large amounts of isotope be given to overcome in some degree the technical difficulties of measurement, and that the optimum time at which definitive information will be obtainable be determined in every case.

THERAPEUTIC CONSIDERATIONS

Biologic alteration of human and other animal tissues by exposure to x-rays and the radiations from naturally radioactive radium was recognized shortly after the discovery of each. One of the earliest reports appeared in the Canadian literature within less than a year following Roentgen's first paper in December, 1895.

The isolation of radium by the Curies shortly thereafter was accompanied by the realization that it gave off somewhat similar radiations (called for some time, "Becquerel rays"), which induced much the same biologic changes on accidental or purposeful exposure.

Clinical observations and some research into relief of pain from local and particularly from confined inflammation, the modification, if not complete disappearance, of certain skin disorders, and the destruction or control of some malignant neoplasms by therapeutic use of these newly discovered physical phenomena were frequently reported in the medical journals at the turn of the century.

Considerable investigation of local effects and also whole body irradiation was pursued by Elihu Thomson, Codman, Barthelmy, Kienbock, and others before the end of the first decade (1895-1905). Many of these early observations formed the basis for fundamental concepts of the biologic effects of irradiation. Although some debate continues as to the selection of cases, in the curable or control

the use of the experienced radiation therapist, who, associated with an able radiation physicist, will continue to critically select suitable cases for such treatment and equally critically assess the results of his ministrations.

Europium^{152, 154} and cesium¹³⁷ may prove to be useful radioactive isotopes for similar use. At this time, cobalt⁶⁰ appears superior when all factors are considered.

Interstitial Irradiation

Tantalum¹⁸² has to have its beta radiation screened with 0.1 mm. of platinum. In wire form it is quite effective in treatment of carcinoma of the bladder and can be used in place of radium, interstitially, in the tongue.

Gold¹⁹⁸ grains, sheathed in stable gold¹⁹⁷ is supplanting the formerly used radon in gold tubing as "seeds" for implantation of small neoplasms. The short half-life, however, requires a short-time-loss relationship to an atomic pile source.

The biologic effect of the gamma radiation from these is the same as that from radium.

Interstitial infiltration of a colloidal suspension of gold¹⁹⁸ into prostatic tissue has been investigated by Kerr, Flocks, Elkins, and Culp in a dose ratio of 2 millicuries/Gm of tissue. Destruction of an appreciable quantity of tumor cells without an undue amount of damage to the tumor bed has been observed. This is still properly in the realm of clinical research, as are some studies by others on parametrial injection.

Intracavity Irradiation

Radioactive isotopes may be used in solid form in the cervix and uterus or in the maxillary antrum for the treatment of carcinoma, as has been done with radium. Here also, cobalt⁶⁰, properly fabricated as discussed regarding interstitial applicators, seems the most satisfactory of the isotopes. It has no advantage over radium, if the latter is available.

Another possible use for a cobalt⁶⁰ source would be as suspended mechanically in the center (or perhaps eccentrically) of a fluid-filled balloon in the urinary bladder for treatment of an extensive vesical carcinoma. Some technical problems of insertion, maintenance

of position, prevention of leakage, and comfort of the patient will arise. Cones and Gregory have found that the tumor dose required is about the same as would be expected with other agents, namely, some 6,500-7,000 roentgens equivalent physical.

Solutions or colloidal suspensions may be used for the treatment of diffuse primary or metastatic neoplasm, within limits:

1. In a hollow viscus, such as the urinary bladder, instead of using the balloon as a means of suspending a gamma radiation source discussed above, the balloon could be filled with a solution of a radioactive isotope salt containing sodium²⁴ (half-life 14.8 hours; beta 1.4 mev; gamma 2.76, 1.38 mev) in sodium chloride, or bromine⁸² (half-life 35 hours; beta 0.46 mev; gamma 1.35, 0.79, 0.55 mev) in calcium bromide.

Technical problems of rapid decay and possible leakage, with contamination of the patient and his environment, must be considered carefully.

2. In the serous cavities (pleura and peritoneum), disseminate implants of metastatic carcinoma (from the breast, ovary, etc.) and the pouring out of serosanguineous effusion, which they induce, can be modified, if not markedly controlled, by the introduction of a colloidal suspension of radioactive gold (Au¹⁹⁸). Our experience has not been as favorable as that reported by some investigators. Some of our relative disappointment has been offset by the appreciation that most of our patients have been rather desperate terminal cases. We have, however, combined the intracavity colloidal gold¹⁹⁸ method with serous-cavity colloidal gold¹⁹⁸ method with external radiation therapy for postoperative patients with carcinoma of the ovary and for others with bronchogenic carcinoma, in which contamination of the space with neoplastic cells during the operation was probable. We are not prepared to comment on the results at this early stage. Theoretically, the method should be useful. The colloidal particles in these suspensions must be too large to pass into the lymphatic drainage channels.

Adjustment of colloid particle size or other means, such as insufflation techniques, or injection of radioactive material via cardiac and pulmonary catheterization, may evolve from

certain research which is in process in various centers, in order to effect local irradiation of selected regional lymph nodes, primary malignant tumors of the lung, or other relatively inaccessible malignancies not amenable to surgical ablation.

Parenteral Administration for Systemic Effect

"Whole-body irradiation" with high voltage x-rays has been used for a long time with considerable success in the management of the chronic leukemias and with less success in polycythemia vera. Similar methods can be used sometimes in widespread multiple myeloma or in diffuse metastatic carcinomatosis (as from the breast) as a palliative measure.

A much more logical and useful attack, especially upon the neoplastic tissue, would be to feed the malignant cells or, as in polycythemia vera, the erythropoietic tissues, some chemical element which they require for life but which would be radioactive and hence irradiate each cell or the tissues as a whole.

The universal requirement for phosphorus on the part of actively reproducing cells, as in the hemopoietic system, would seem to make its radioactive isotope (P^{32}) an ideal element for this purpose.

This has been proved useful, especially in polycythemia vera and in multiple myelomatosis. However, as has been noted above, the rapid turnover of phosphorus in cell metabolism and the side effects of general irradiation of the whole organism present problems which are similar to those associated with the use of cytotoxic or cytodepressant drugs (urethane, nitrogen mustard, etc.) and general roentgen irradiation.

Such treatment should be reserved for the use of the experienced radiation therapist working closely with the hematologist. The dosage must be adjusted to the individual patient. No standard rules have yet been evolved as to either the minimum safe dose or the maximum tolerable dose.

At present, in the authors' opinion and experience, the maximum initial dose of P^{32} should not exceed six millicuries. This should be given in divided doses in multiple myeloma. In polycythemia vera, a second dose, of any

magnitude, should not be considered short of 3 months.

As one of us has previously pointed out, "further development of possible systemic therapeutic agents incorporating radioisotopes will require greater knowledge of physiologic chemistry and cell metabolism than we presently have."

Parenteral Administration for Specific Organic or Cellular Effect

"Specific internal irradiation," or the use of selected radioactive isotopes for potential specific effect upon an organ or cell type is best exemplified in the treatment of hyperthyroidism or of cancer of the thyroid with I^{131} . Specific internal irradiation is accomplished in polycythemia vera or multiple myeloma with P^{32} , as applied to widespread tissue which perhaps could be considered as one organ. However, the special and almost exclusive use of iodine by the thyroid gland affords unusual opportunity to affect the thyroid cells specifically with the local irradiation of the decaying radioactive iodine.

Criteria as to specificity of physiologic usefulness and nontoxicity of the selected clinical element have been stated earlier in this chapter.

The physiologic use of iodine by the thyroid as an iodide ion has been discussed in some detail above, in order that the reader may understand the physiologic cycle of iodine use by the thyroid and appreciate that it can effect local irradiation while in the extracellular fluids of the gland, especially in the thyroid cell and its colloid.

The indications for treatment with I^{131} are as follows.

- 1 Hyperthyroidism in
 - a. Patients over 40-45 years of age
 - b. Younger patients in whom antithyroid drugs have failed to effect control or have induced deleterious side effects, or surgical methods have been refused
 - c. Patients who have associated cardiovascular disease which does not respond to other means of treatment
 - d. Patients with recurrence after surgical intervention
- 2 Thyroiditis, acute
- 3 Carcinoma of the thyroid, if the malignant cells or their immediate tumor bed normal cells will take up adequate amounts of the radioactive isotope

RADIOACTIVE ISOTOPES

The contraindications for I^{131} treatment of hyperthyroidism agreed upon at the present time in this hospital are as follows:

1. Acute hyperthyroidism in younger patients
2. Hyperthyroidism during pregnancy
3. Nodular goiter

Opinions vary as to the optimum therapeutic dose in nonmalignant thyroid disease. The individual patient's utilization of the iodide 131 as studied with tracer amounts must be known and considered. At present, we consider a standard initial dose preferable, with supplemental administration in 3-4 months, as required.

Careful assay initially and a thorough reassessment are essential before any additional treatment.

It must be emphasized that in the hands of the experienced radiation therapist, equally effective treatment (as to clinical results) can be accomplished with properly administered conventional x-radiation. Pregnancy and youth are *not* contraindications for x-ray therapy of the hyperactive thyroid.

In malignant disease of the thyroid, the frequently relative disinterest of cancerous thyroid tissue in the use of iodine has been an obstacle, preventing material initial uptake of the radioactive isotope and any appreciable retention by the thyroid gland and its cells. Little advance in surmounting this hurdle has been made since Hamilton's first observation and Seidlin's initial report on treatment.

About 10% of the malignant thyroid tumors will use appreciable iodine.

Large doses of I^{131} are required for any effective treatment of cancer of the thyroid. In the majority of such patients, the discard of the isotope in the urine will be of a high order and will require careful observance of isotope isolation and noncontamination regulations.

In many of such malignant cases, external roentgentherapy can be used as effectively as and probably more effectively than specific internal irradiation with I^{131} .

Until more is known of specific cell metabolism and its biochemistry, especially with reference to any particular factor vital to the life of the malignant cell, employment of radioactive isotopes for specific internal irradiation must be confined to the select few discussed above.

The use of direct neutron irradiation to affect previously injected boron in treatment of brain tumors is being investigated at the Brookhaven center. This may in time be found to be useful but is still in the realm of research.

It is to be hoped that as knowledge of the radioisotopes grows, combined with increased interest in basic and especially clinical physiology, the use of these tools will advance our understanding of the normal and the abnormal state, and in turn result in more intelligent diagnosis and control of disease.

Chapter 8

Anesthesia

Richard G B Gilbert, MB, Alan B. Noble, MD,
and Philip R Bromage, MB

INTRODUCTION

As in the case of all other branches of medicine and surgery, the practice of anesthesia must be based upon a thorough appreciation of the great principles laid down in the study of the basic sciences. Added to this, attention must be paid to the psychologic approach to and the handling of patients.

For successful anesthesia three things are essential: the patient must feel no pain, conditions must be satisfactory for the surgeon, and no harm must befall the patient. In other words, there must be analgesia and suppression of reflex responses to surgical trauma, and the *milieu interne* must be maintained constant in the face of modifications of normal anatomy and physiology arising out of the nature of the operation or the anesthetic. For example, during thoracic surgery problems of the open pneumothorax must be dealt with by rhythmic artificial inflation of the lungs in order to correct mediastinal shift and paradoxical respiration. During operations on the nose and throat the airway must be made watertight to prevent the patient drowning in his own blood. When complete muscular paralysis is induced by curare-like substances in order to provide a quiet surgical field, the accompanying apnea must be corrected by adequate artificial respiration, and so on.

During recent years there has been a growing realization that deep general anesthesia

■ harmful. Enzyme systems throughout the body are depressed and the functions of various parenchymatous organs disturbed for long periods after deep anesthesia. Furthermore, cardiovascular depression occurs with the onset of a shocklike state.

For many years it was thought that anesthesia had to be carried to reasonable depths to avoid the occurrence of neurogenic shock; otherwise the continued bombardment of the central nervous system by fierce afferent stimuli would cause exhaustion of the central nervous system. This gave rise to Crile's theories of anoci-association—the blockade of afferent stimuli by local anesthesia, combined with light general anesthesia to prevent psychic disturbances. While techniques based on Crile's theories gave excellent results compared with cases carried out under deep general anesthesia, it was not for the reasons that Crile supposed. Since the introduction of the neuromuscular blocking agents, such as curare, concepts of neurogenic shock based on Crile's theories have had to be modified. It has become apparent that the most destructive procedures can be done without any afferent blockade and under extremely light general anesthesia (so light that the patient can respond to the spoken word) and yet, provided there is muscular paralysis and provided blood loss is replaced by blood, no shock appears. Almost anything can be done to the patient so long as he can make no effective response.

ANESTHESIA

The reasons for this are probably quite simple. The nonspecific pattern of response to trauma is an expiratory grunt or groan, as the sensitive organism tries to protect itself by constricting its thoracic and abdominal muscles as a shield against dangerous stimuli. This forced expiratory pattern causes a diminution of thoracic compliance and a rise of venous pressure. The former increases the work of respiration, and the latter diminishes the perfusion pressure across tissue capillary beds, increasing any stagnant anoxia present and enhancing bleeding from cut surfaces. Thus, it is not the surgical trauma which

does the harm, but rather the patient's own instinctive, but, under the circumstances, inappropriate pattern of responses. If the patient can be protected from himself by muscular paralysis, if as St. Paul puts it, there is no kicking against the pricks, afferent bombardment appears to have little effect on the clinical condition of the patient.

Thus, with few exceptions, deep anesthesia is seldom necessary, provided suppression of reflexes is obtained by other methods, for the reflex arc can be broken in any part of its course by either sensory or efferent blockade

TABLE 8

Emancipation from the need to employ deep anesthesia carries many advantages. Depression of hepatic, renal, and cardiovascular function by high concentrations of anesthetic agents is avoided, and light anesthetic "sleep" can be carried on for many hours without detriment. Prompt arousal at the end of operation simplifies postoperative care, for the patient is in full possession of his protective swallowing and coughing reflexes, and he can control his own posture. Moreover, if postoperative coma is prolonged for any reason (e.g., electrolytic imbalance, intracranial lesions, etc.), the diagnosis is not confused by the added factor of prolonged recovery from deep anesthesia.

In addition to those actions shown in the scheme, some drugs affect the spinal reflexes, some the internuncial neurons, and some the reticular activating substance.

Secondary Action of Anesthetic Drugs

Respiratory System.—Drugs may depress or stimulate the nervous mechanism by which respiration is controlled either centrally or peripherally, in a manner which may interfere with ventilation to any degree from hyperventilation to apnea. In addition, the bio-chemical influence of the blood gases and pH by their action upon the respiratory centers and chemoreceptors may affect ventilation.

Fig 48—Primary action of general anesthetic drugs. A, Depression of polysynaptic relays in reticular formation of mid- and hind brain blocks projection of afferent impulses to cortex. (Gradation in shading denotes degree of depression.)

BASIC CONSIDERATIONS

PHARMACOLOGIC OBSERVATIONS

Action of Drugs Upon the Nervous System

As all anesthetic drugs and those used in association with anesthesia act on the nervous system, it is appropriate to differentiate the effect of some graphically (Table 8) in an endeavor to show at what site this action takes

The bronchial muscle may be stimulated or depressed, resulting in bronchial constriction or bronchial dilatation.

The mucosal lining of the air passages may be irritated, resulting in the production of excessive secretions, unless an anticholinergic drug is given to depress the glandular activity.

Cardiovascular System.—Drugs used in anesthesia and anesthetic techniques may in-

Fig 50 - Simplified diagram of nervous control of heart

Fig 51—Effects of anesthesia on alimentary tract

Fig 52—Innervation of the gastrointestinal tract

fluence the activity of the cardiovascular system. Such phenomena produced may be (1) brought about by a direct nervous mechanism, e.g., action of atropine on the vagal nerve endings in the heart muscle; (2) caused by oxygen lack or carbon dioxide excess, e.g., pressure changes, cardiac arrhythmias, or even cardiac standstill; (3) induced by the direct action of drugs on the heart muscle, e.g., sensitization by cyclopropane, (4) the result of the response of the coronary vessels, e.g., coronary constriction caused by Pitressin; (5) caused by responses to pressoreflexes or chemoreflexes, (6) produced by the action of drugs on the vasomotor center, e.g., peripheral vasodilatation and subsequent diminution of peripheral resistance; (7) due to action on the blood itself, e.g., hemoconcentration; (8) caused by temperature changes.

Alimentary System.—The commonest side effect in this system is the nausea and/or vomiting which may be caused by anesthesia. This may be produced by either central or local action.

The autonomic ganglia within the abdomen are extremely sensitive structures, the stimulation of which under inadequate anesthesia may result in unpleasant and even serious responses.

The numerous functions of the liver may be depressed by anesthetic drugs, by anoxia, or by hypotension. Among these functions is that of detoxifying or conjugating some of the agents used. Anoxia readily interferes with these functions, while some drugs may have a specific effect upon the liver. The adverse effect of drugs upon the liver is increased by oxygen lack (Figs 51 and 52).

Other Systems.—The effect of anesthetic drugs or techniques may be reflected in other systems. For instance, the secretion of urine is usually depressed by general anesthesia, the antidiuretic hormone being stimulated and renal blood flow diminished.

Spinal anesthesia is more commonly followed by retention of urine than is general anesthesia.

PHYSIOLOGIC OBSERVATIONS

Respiratory System. The change of conditions accompanying anesthesia and surgery may so alter the mechanics of respiration that oxygen uptake and carbon dioxide elimination may become inadequate to maintain the narrow

biochemical limits compatible with life. Therefore it is important to have a clear picture of the normal ventilatory requirements and the alterations of respiratory mechanics that may have to be corrected or allowed for during a surgical operation.

RESPIRATORY GAS EXCHANGE.—The normal adult utilizes about 250 ml. of oxygen each minute, and in the same period he excretes about 90 mEq of acid in the form of exhaled carbon dioxide (with a respiratory quotient of 1.0 this will be contained in 250 ml CO_2). Since expired air contains 4% carbon dioxide, elimination of this quantity of CO_2 will require a minute volume of at least: $250 \times 100/4 = 6,250$ ml. (i.e., 6.25 L.). Therefore, if the patient is breathing spontaneously, the minute volume should never be allowed to fall below this level, and the inflow of fresh anesthetic gases must be kept in excess of this in order to flush out exhaled CO_2 from the circuit. If a carbon-dioxide absorber of soda lime is in the circuit, the inflow of gases can be reduced to the basal requirements.

If respiration becomes depressed for any reason, so that the minute volume falls below about $6\frac{1}{4}$ L., ventilation must be augmented artificially by applying an intermittent inflatory pressure to the rebreathing bag, the rhythm being timed to accord with the patient's own respiratory rate (this is called "assisted respiration"). Or, alternatively, the patient's own rhythm can be abolished by hyperventilation combined with respiratory depressant or paralyzant drugs, and an entirely different respiratory rate and depth can be imposed (this is called "controlled respiration"). Provided no noxious stimuli are entering the central nervous system, controlled respiration is surprisingly easy to impose under very light anesthesia, using hyperventilation alone. However, if painful stimuli are being received, the patient reacts by tightening his thoracic and abdominal muscles, and anesthesia must be deepened, or a paralyzant drug given, to overcome this reactive spasm of the expiratory muscles.

Once spontaneous respiration has been abolished, inflation of the lungs follows an abnormal pattern, since the alveolar tree is opened up by positive pressure from within instead of by the peripheral negative pressure avail-

ated with normal spontaneous respiration. This reversal of the normal inflationary pattern is accompanied by a considerable fall in pulmonary compliance. That is, a greater pressure has to be used to shift a given volume of tidal air, and an abnormally large minute volume has to be maintained in order to ensure adequate elimination of CO_2 . Thus, the anesthetist should err on the side of overventilation rather than underventilation when using controlled respiration, in order to avoid an insidious accumulation of carbon dioxide and an accompanying fall of pH of the blood to dangerously acidotic levels. For, under these circumstances, vagal tone is heightened and then cardiopressor reflexes may bring about cardiac arrest from relatively trivial stimuli, such as the removal of an endotracheal tube at the end of operation, which would normally produce no appreciable effect. Overventilation, on the other hand, seldom leads to trouble.

DEAD SPACE—Children require special care to ensure efficient respiratory exchange. In children the ratio between the volume of the air passages and the alveolar volume is large compared to that of adults, so that each breath contains a relatively large amount of "dead space air," that is, gas which does not take part in the respiratory exchange, since it occupies the air passages and does not reach the alveolar membrane. If rapid shallow breathing is allowed to develop in these patients, anoxia can quickly follow, since with shallow breathing the tidal volume approaches the dead space volume and all that happens is a shunting to and fro of functionless dead space air. For this reason, drugs such as trichloroethylene, which tend to cause rapid breathing, should be avoided in children.

It follows also that an apparatus which increases the dead space is harmful. Face masks should be designed to contain as small a volume as possible, and in long operations it is wise actually to reduce the normal dead space by inserting an endotracheal tube. In cases where severe respiratory embarrassment exists (e.g., copious bronchial secretions or partially paralyzed respiratory muscles), elective tracheostomy is an excellent way of reducing the dead space and improving respiratory efficiency.

RESISTANCE TO BREATHING.—Increased resistance to respiration not only increases the work necessary to breathe but also causes a rise of venous pressure which in turn increases surgical hemorrhage from cut tissues. Therefore, attention must be directed to keeping this resistance to a minimum at all times. Absence of respiratory resistance can contribute a great deal toward reducing blood loss during operation. Increased resistance to breathing can arise in the following sites:

Air Passages—Partial or complete obstruction to the airway has numerous causes, such as excessive secretions, laryngeal spasm, a relaxed tongue which has fallen backward, etc. Besides bearing in mind these common hazards, it is well to remember a few basic principles concerning the flow of gases in tubes, for their application provides a guide to good anesthetic technique.

Flow in tubes is proportional to the fourth power of the diameter; thus a small amount of laryngeal or bronchial spasm can have a profound effect on respiratory resistance and respiratory exchange; by halving the diameter of a bronchus the resistance will increase 16 times. Therefore every effort should be made to provide a relaxed bronchial tree. Ether, aminophylline, and topical anesthesia should be considered in cases of bronchospasm, while Pentothal should be used with caution, if at all, in such cases.

Apparatus—The foregoing remarks qualify the choice of endotracheal tubes which should therefore be as large as the larynx will comfortably admit. The lumen of such tubes should be as great as possible, concomitant with the rigidity of the wall.

In straight or curved tubes, flow is laminar and resistance is proportional to flow rate, but with turbulent flow, resistance is proportional to the square of the flow rate. Therefore, endotracheal connections should be curved and not angled, and any kinking of the breathing tubes should be rigorously avoided.

Most anesthetic machines have expiratory valves to permit the escape of excess anesthetic gases; these valves possess resistance. If perfect conditions are sought, these valves can be discarded in order to ensure complete lack of extrinsic resistance, and the patient may be

supplied with a high flow of anesthetic gases, the excess passing out into the room through an open-end tube

Lung and Chest Wall—The natural respiratory response to painful noxious stimulation is a forced expiratory grunt, as the thoracic and abdominal muscles tense into a shield over the underlying viscera. This same reflex is brought into action by stimulation of the tracheobronchial tree; for example, by the presence of an endotracheal tube. Too light anesthesia allows this protective reflex to take effect, and the patient then has to breathe against his own increased muscular resistance. Besides increasing the amount of work required for respiration, this also raises the venous pressure and increases surgical hemorrhage.

This adverse reflex can be abolished in exactly the same way as other reflexes, by attacking it centrally with deeper anesthesia or peripherally on the afferent or efferent side of the reflex arc with regional anesthesia or neuromuscular blockade.

The lung parenchyma, itself, may become abnormally stiff and resistant, as in pulmonary congestion from cardiac failure or from over-enthusiastic administration of blood and other intravenous fluids.

SIGNS OF RESPIRATORY INADEQUACY—Cyanosis is mentioned more fully elsewhere in this chapter. Except in polycythemia, it is a relatively late sign of anoxemia requiring urgent correction of the underlying cause.

Early anoxia causes a full bounding pulse which gives way later to a failing, thready beat. In infants, bradycardia may be the first sign of anoxia to appear, and this should be treated at once by inflating the child's lung with oxygen. A rising systolic pressure and widening pulse pressure may be warnings of carbon-dioxide accumulation due to underventilation or to an inadequate flow of gases to flush exhaled CO_2 from the anesthetic circuit.

Sweating is most commonly due to either CO_2 retention or to gross afferent stimulation in the presence of inadequate anesthesia or muscular relaxation. An increased minute volume and improved compliance will usually correct sweating.

Obstructive signs of respiratory obstruction may be audible or visible. Low-pitched snoring

sounds commonly originate above the larynx, due to the tongue or epiglottis falling back and blocking the glottis. High-pitched inspiratory stridor is usually due to partial laryngeal spasm, which should be corrected by deepening the anesthesia or by passing an endotracheal tube under direct vision. During laryngoscopic inspection the anesthetist can determine whether the obstruction lies at the cords or beyond, e.g., tracheal obstruction from a retrosternal goiter. Moist rales indicate the presence of bronchial secretions, and these should be removed by passing a bronchial aspiration catheter through the endotracheal tube. Lack of movement of the rebreathing bag spells respiratory paralysis, obstruction, or an endotracheal tube which lies in the esophagus. If obstruction is the cause, each abortive inspiration will be accompanied by indrawing of the suprasternal fossae.

A continuous electroencephalographic recording can be useful for the early detection of cerebral anoxia in difficult cases. Cerebral cellular anoxia from anoxemia, arterial hypotension or hypoglycemia, and a deep general anesthetic itself, all produce a nonspecific pattern of electric depression in the EEG. The normal wave pattern of light anesthesia is replaced by slow waves of between 0.2-2.0 cycles/second, and later the pattern flattens out to complete electric silence. If very light levels of anesthesia are employed, then any depression of electric activity must be due to cerebral anoxia or hypoglycemia, and the cause can be quickly sought out and corrected.

Cardiovascular System.—The cardiac output depends upon a number of factors. Then must be considered the efficiency of the heart muscle, the valves, the coronary circulation, the conducting tissue, and the cardiac nerve. The hematologic, biochemical, and physiologic qualities of the blood must be within normal limits. The blood vessels should present no marked disease. The physiologic responses to vascular reflexes should be active, and finally, in some respects, there must be normal endocrine balance.

The integrity of the cardiovascular system presupposes a normal respiratory system, for there must be perfect oxygenation and adequate carbon dioxide elimination.

Blood pressure depends upon the cardiac output, the peripheral resistance, and the viscosity of the blood. During anesthesia, blood pressure fluctuations may occur. These reflect the basal fall due to vasodilatation and the compensating mechanisms trying to correct it. Observation of the pressure may detect a number of incidents, some associated with anesthesia, others not.

The *pulse* of an anesthetized patient may vary. These variations should be interpreted in conjunction with the blood pressure determinations. Specific types of rhythm may be noted.

From blood pressure and pulse observations such things as oxygen lack, carbon-dioxide accumulation, autonomic nerve stimulation, hemorrhage, shock, and responses to various other vascular reflexes may be deduced. Such observations are interpreted in the light of responses by the respiratory system, which give additional information.

Unless otherwise indicated, the blood pressure of a patient during anesthesia should be maintained in the neighborhood of its usual level. Factors responsible for a fall, such as hemorrhage, should be appropriately corrected.

Patients who are on cortisone therapy should have this continued during and after anesthesia and surgery. Those who have received it prior to surgery but to whom its administration has been discontinued should be carefully considered as possibly requiring intravenous cortisone therapy during anesthesia. Under these circumstances the previous treatment may have suppressed the patient's own cortical secretions. If this be the case, the stress of anesthesia and surgery may not be tolerated, and a persistent fall in blood pressure will follow which can be controlled only by cortisone.

Cyanosis, which is the visual index of the absolute quantity of reduced hemoglobin in the blood, is evident when there are at least 5 Gm/100 ml circulating. In the case of the individual with a normal blood count the hemoglobin will be approximately 80% saturated when cyanosis becomes apparent. It is not a sign to await in anesthesia, as anoxia may be present before cyanosis develops. In a polycythemic subject, however, it may not indicate hypoxia, while in the grossly anemic patient cyanosis cannot appear. Under certain

circumstances, cold for example, cyanosis may be seen locally; it is due to the narrowing and therefore stagnation of the vascular bed. This type of cyanosis is not indicative of anoxic anoxia.

Pallor may be observed in a patient who is known to be anemic, in one who has suffered severe blood loss, or in one who is in shock. In the latter two instances it is the result of compensatory vasoconstriction; this is also true of pallor occurring in that part of the body unaffected by a high spinal or epidural anesthetic.

The vessels in the nail bed should not only be watched for color changes but also tested for *capillary tone* by pinching. Capillary tone is diminished by deep anesthesia, as the vessels are paralyzed, while in shock there is vasoconstriction; both lead to a decrease in circulating blood.

Alimentary System.—The nerve supply of the gut is autonomic. The sympathetic portion influences the gastrointestinal tract in its entirety. The parasympathetic, however, although having an over-all influence, is divided into a sphere of vagal distribution, descending as far as the inferior mesenteric plexus and that of the sacral parasympathetic which, via the superior and inferior hypogastric plexus, innervates the lowest portion of the bowel.

A general anesthetic may, depending upon its depth, diminish the tone of the bowel and cause relaxation of the sphincters. A spinal anesthetic, on the other hand, will paralyze the sacral parasympathetic nerves and the sympathetic nerves up to the height to which it extends. The vagus nerve, however, will be unaffected and its action unopposed.

Other Systems.—In anesthesia for genito-urinary surgery it is important to know the segmental nerve distribution. Likewise in obstetric anesthesia it is of extreme importance to have an accurate knowledge of the motor and sensory innervation of the uterus and birth canal.

PRACTICAL CONSIDERATIONS

PREPARATION OF THE PATIENT FOR ANESTHESIA

The administration of an anesthetic should not be lightly undertaken. The induction

general anesthetic or the production of conduction analgesia is a major procedure.

The anesthetist should visit the patient prior to operation, elicit a history of previous illnesses and anesthetics, examine the patient, check urinalysis and hemoglobin, and then decide what preoperative medication and anesthetic management are most suitable for that patient undergoing that particular procedure.

In cases of election it is advisable to prescribe a barbiturate to ensure sleep the night before the operation. The combination of a quick-acting barbiturate with one of longer duration may be considered.

At the time of this examination the anesthetist prescribes certain drugs to be given before the patient goes to the operating room and leaves instructions concerning the general preparation, such as the withholding of food and fluid for 6-8 hours prior to anesthetic. He also takes this opportunity to reassure the patient. In certain cases such as diabetes, myasthenia gravis, or thyrotoxicosis, in patients being treated with cortisone, or in those whose hydration, acid-base balance, or blood volume is at fault, specific additional preoperative instructions may be necessary. Such may require consultation and additional help from other departments.

In the case of surgical emergencies, the premedication may have to be modified. The intravenous route for the administration of the premedicant drugs, with suitably modified dose, may be considered. Frequently the emptying time of the stomach is delayed in such patients. This factor may alter the choice of anesthetic technique and may affect the management of the case. It may even be necessary under certain circumstances to wash out the stomach prior to the induction of anesthesia. It can be emphasized here that vomiting during induction or emergence from anesthesia gives rise to greater mortality and morbidity than any other single factor.

Premedication Drugs.—Commonly, a narcotic such as morphine, Demerol, Pantopon, or Methadone or an hypnotic such as one of the short-acting barbiturates is given either alone or in combination to relieve anxiety, diminish pain, and produce a state of drowsy relaxation. Such a state permits the pleasant induction of anesthesia, lessens the quantity of toxic drugs

necessary to maintain anesthesia, and counteracts the undesirable side effects of the anesthetic. It should be noted that when pain is a feature of the preoperative condition, the use of a hypnotic alone will serve only to aggravate the condition by producing restlessness, for a hypnotic in the usual dosage has no analgesic action. It may also be noted that the use of some of these drugs may produce side effects which are undesirable; such an effect is the constipation which follows the use of morphine.

In addition to the sedative, either atropine or hyoscine is given. The anticholinergic action of these drugs depresses vagal activity, thereby diminishing bronchial secretions and lessening the vagal reflex responses of the heart. Hyoscine has yet another effect, that of producing amnesia.

The dose of these drugs is chosen according to the weight, age, and general condition of the patient, the presence of fever or an altered basal metabolism rate is also taken into account. Premedication drugs are usually given subcutaneously about one hour prior to the induction of anesthesia.

Avertin (2.5%, prepared according to instructions; 50-100 mg/kg.) or a solution of an ultrashort-acting barbiturate (Pentothal, 40 mg/kg in a 10% solution) may be given rectally, together with atropine or scopolamine subcutaneously, 30 minutes before anesthesia, to provide basal narcosis in very nervous subjects or in the young.

GENERAL ANESTHESIA

Analgesia means loss of sensation to pain without unconsciousness.

Anesthesia means loss of all sensation. Under general anesthesia there is also loss of consciousness. The types of anesthesia are described as (1) general and (2) conduction.

Discussion.—Generations of students have been brought up on the signs of anesthesia laid down by Guedel; these are described in terms of three stages, the third being that of surgical anesthesia, which in turn is subdivided into four planes depending on the depression of respiration and other reflex responses. It is not sufficiently appreciated that these signs were originally described for ethyl ether, and

Fig 31—Anesthesia apparatus

TABLE 9 PROPERTIES OF INSULATION AGENTS

AGENT	SP GR	R.P.	PHYSICAL CHARACTERISTICS	POTENCY	MUSCULAR RELAXATION	INFLAMMABLE	REMARKS
Chloroform CHCl_3	Liquid 1.76 Vapor 1.12	61° C	Colorless oily fluid Sweet smell Irritates skin Vapor nonirritating	Very strong Blood conc 16 mg %	Extreme	No	Lowers pulse pressure. Diminishes cardiac output. Stimulates heart muscle. NEVER USE WITH EPINEPHRINE. May cause primary cardiac arrest. Toxic effect on liver. Causes nausea and vomiting. Causes acidosis.
Ether Diethyl ether $(\text{C}_2\text{H}_5)_2\text{O}$	Liquid 0.71 Vapor 2.6	34.5° C	Colorless fluid Pungent smell Irritating to skin and mucous membranes	Strong Blood conc 75 mg %	Good	Yes	Increases cardiac output (except when deep). Raises pulse pressure. Causes nausea and vomiting. Causes acidosis. Sympathomimetic.
Vinethene Divinyl ether $(\text{C}_2\text{H}_3)_2\text{O}$	Liquid 0.77 Vapor 2.2	28.5° C	Colorless fluid Musty smell Nonirritating	Strong Blood conc 40 mg %	Good	Yes	Suitable for induction, especially in children. Causes salivation.
Trilene Trichloroethyl- ene $\text{C}_2\text{HCl}_2\text{CCl}_3$	Liquid 1.15 Vapor 1.5	87° C	Colorless fluid (blue added) Sweet smell Liquid irritating Vapor nonirritating	Use only at anesthetic conc.	Poor	No	Should only be used as an analgesic. Deeper stages cause tachypnea and arrhythmia. DO NOT USE WITH SODA LIME. Rarely causes nausea or vomiting.
Ethyl chloride $\text{C}_2\text{H}_5\text{Cl}$	Liquid 0.912 Vapor 2.58	12.5° C	Colorless fluid Disagreeable smell Very volatile Nonirritating	Strong Blood conc 25 mg %		Yes	Formerly used for induction. May cause arrhythmia. May cause laryngeal spasm. Causes nausea and vomiting.
Nitrous oxide N_2O	1.1	89° C	Colorless gas Sweet smell Nonirritating	Very weak Blood conc 25 vols %	Poor	No	Used for induction short cases or combined anesthesia.
Fiblenone C_8H_8	978	-105° C	Colorless gas Foul smell Nonirritating	Weak Blood conc 150 mg %	Poor	Yes	Not often used. More expensive than N_2O . Gives everyone in the operating room a headache.
Cyclopropane C_3H_4	1.1	-31° C	Colorless gas Sweet odor Slightly irritating	Strong Blood conc 13 mg %	Fair	Yes	Parasympathomimetic. Stimulates heart muscle. NEVER USE WITH EPINEPHRINE. Depresses respiration markedly. May cause cardiac arrhythmia. May cause nausea and vomiting. Rapid induction. Rapid elimination.

Pontocaine (Tetracaine, Amethocaine, Decicain).—Pontocaine, as procaine, is an amino benzoic acid derivative. The structure of its salt is dimethylaminoethyl-para-N-butylaminobenzoate hydrochloride. Its introduction in 1933 resulted from efforts to produce a local anesthetic drug with topical activity which is capable of producing more prolonged local or regional analgesia than that produced by procaine. It proved to be successful in both respects. The anesthetic potency of pontocaine is about 10 times that of procaine and, in concentrations commonly used for procaine, it is proportionately toxic. However, its potency allows for analgesic efficiency in much weaker dilutions. Bonica has assessed its corrected toxicity ratio (in mg/kg. body weight corrected for dilution) as 0.6 that of procaine, with an associated anesthetic index of 1.6 when compared with the same drug (See Table 10.)

TABLE 10*
PONTOCAINE VOLUME AND CONCENTRATION

USE	CONCENTRATION	VOL. ML	MG
Local infiltration	0.025%	200-300	75-100
Field block	0.05%	150-200	75-100
Small nerve block	0.1%	100-125	100-125
Block of larger nerves, plexus blocks, and epidural blocks	0.2%	50-60	100-125
Spinal block	0.3-0.5%	3-5	10-20
Topical application	1-2%	2-3	20-40

*From Bonica, J. J. *The Management of Pain*, Philadelphia, 1953, Lea & Febiger

Xylocaine (Lidocaine).—Xylocaine, an acetanilide derivative, represents the best addition to this type of drug in recent years.

The drug is extremely active when used either topically or by infiltration. It is non-irritant, soluble, and heat stable. Onset of analgesia is rapid and the degree is profound and prolonged. The systemic toxicity is little more than that of procaine.

For topical anesthesia of the larynx the optimum concentration is 4%. For nerve blocks and caudal and epidural blocks 1-2% solutions are used. Epinephrine may be added to produce the desired vasoconstriction with increasing duration of action, at the same time reducing the rate of absorption.

In comparison with other agents, most authorities report a higher incidence of successful blocks and a more profound analgesia when Xylocaine is used.

Nupercaine (Percaine).—This drug is a quinoline derivative and is the longest acting of all local anesthetic agents in common use. On a mg/kg body weight basis it is 20 times as toxic as procaine. This toxicity is compensated for by its anesthetic activity in high dilution. For topical use 0.5-1% may be used in small quantities. In the urethra, 1% is not safe because of the possibility of rapid absorption. For infiltration anesthesia, a solution of 1:2,000-1:4,000 is satisfactory. For nerve block procedures, a solution of 1:1,000-1:1,500 gives good results. For spinal anesthesia, a solution of 1:1,500 is made up in 20 ml. ampules, which has been used for many years according to the techniques described by Jones and Wilson. For low spinal anesthesia, a 1:400 solution in dextrose is available.

The relative safety of this drug results from its potency and subsequent anesthetic activity in high dilutions, which results in a lower corrected toxicity.

A hazard has arisen as a result of the similarity of the name with procaine. Pharmacists have, on occasion, confused 2% percaine with 2% procaine, a mistake which has produced fatalities.

Types

Topical.—The drug is applied to a mucosal surface where it anesthetizes nerve endings.

Local Infiltration.—The drug is injected and affects the nerves with which it comes in contact. This method is applicable to minor procedures, such as the excision or biopsy of small tumors, or for suturing lacerations. A vasoconstrictor is usually added to prevent rapid absorption of the anesthetic drug and to diminish hemorrhage.

Field Block.—The terminal branches of the nerves are blocked by injecting a wall of local anesthetic along the borders of the area they supply. A continuous intradermal wheal is followed by gradual infiltration of deeper tissue planes to any required extent.

Nerve Block.—The nerves are blocked at any convenient point along their course to the periphery of the body before they are divided.

PRACTICAL CONSIDERATIONS

Fig. 57—Regional nerve block anesthesia for upper extremity

Fig 38--Regional nerve block anesthesia for lower extremity (See Fig 139 for lumbar, sacral, and pudendal plexuses)

into their terminal branches. Efficient nerve blocking requires accurate anatomic knowledge. Any sensory nerve may be blocked, but for many the landmarks are variable and difficult to define accurately. The addition of hyaluronidase to the local anesthetic drug is no excuse for an inaccurately placed injection. Although hyaluronidase destroys the cement substance in the tissue architecture, it will not diffuse between tissue compartments and it will weaken the local concentration of the drug by increased diffusion.

Paravertebral Block.—The spinal nerves are blocked as they emerge from the intervertebral foramina or in the vicinity of the vertebrae. A paravertebral block may be performed at any level of the spine and used for diagnostic or anesthetic purposes.

Epidural Analgesia.—The spinal nerves are blocked in the epidural space. This procedure may be carried out at any spinal level; most commonly L2-3 and L3-4. It provides analgesia similar to that produced by a spinal anesthetic but is slower of onset. Sympathetic paralysis may be complete, while sensory loss may be made to extend to the jaw; motor paralysis may be less profound.

Spinal Analgesia.—

PRINCIPLES.—The spinal nerves are blocked within the dural space. Both anterior and posterior roots are affected. The extent of the analgesia produced from a relatively small dose of analgesic drug is much greater than can be obtained by a similar dose using any other regional technique. Spinal analgesia can be used for operations anywhere below the clavicles but is commonly reserved for operations below the diaphragm. It provides ideal conditions for abdominal operations or operations on the lower extremities but should not be administered by an unskilled person without adequate supervision.

There is a great variety of drugs available for spinal analgesia. Those most frequently used are procaine (Novocain), Pontocaine, and Nupercaine. The drug selected may be used either as a hypobaric, hyperbaric, or isobaric solution. The type of solution depends on the technique that is to be employed, since most techniques of administration rely to a certain extent on gravity control of the range of

spread of the anesthetic effects and to a lesser degree on the volume injected and rate of injection. The duration of their effects varies with different drugs, but with the same drug the duration may be affected by the concentration, the total dose of the drug injected, or by the addition of a vasoconstrictor. The analgesic effect following the administration of procaine is approximately 1 hour, of Pontocaine 2 hours, and of Nupercaine 3 hours.

In order to be able to provide spinal analgesia of longer duration the *continuous* spinal technique was introduced by Lemmon, employing a malleable needle and a split mattress. Any of the local anesthetic drugs may be used in the continuous spinal technique, but procaine, Pontocaine, and Metcaine are those which are used most frequently.

The continuous technique may also be employed in a somewhat similar manner in epidural analgesia to provide prolonged analgesia. A popular form is the continuous caudal technique utilized in obstetrics.

Toohy modified this method, using a Huber tipped lumbar puncture needle, through which is passed a No. 3½ gauge ureteral catheter or vinyl plastic tube. This catheter or tube can, with care, be passed to any desired height. It can also be used in the epidural space, a method which carries less morbidity than that by the subarachnoid route.

TECHNIQUE.—

Ascertain that a spinal anesthetic is one of choice and premedicate accordingly.

Preparation of Equipment.—All instruments, ampules, files, etc., must be autoclaved. All drugs used in this procedure must be fresh preparations, and the ampules in which they are contained must be checked. It is advisable to use only those ampules on which the description is etched and not printed. The lumbar puncture needle should not be larger than No. 20, finer ones may be used when the technique has been mastered. The needle should be tested before the puncture by running through a piece of gauze. Full sterile technique should be observed by the anesthetist.

Preparation of the Patient.—The correct posture is imperative if lumbar puncture is to be

simple and atraumatic. The back is painted with iodine or suitable substitute and then draped. Anesthetic solution should then be infiltrated at the elected site. This should not be higher than L2-3, while a puncture can be satisfactorily performed as low as L5-S1; the commonest level is L3-4 which is the first space above the intercristal line. If a vasopressor is deemed advisable, as for instance in the case of a "high spinal" to counteract an anticipated fall in blood pressure, it should be given at this time, along with the infiltrating drug. Vasoxyl 10 mg is frequently considered

the vasopressor of choice as it does not stimulate the central nervous system as does ephedrine.

The Puncture—A lumbar puncture is then made. A midline puncture is usually the most simple and the least traumatic. In performing this, the anesthetist should familiarize himself with the various resistances met by the needle as he pushes it inward: (1) the skin; (2) the interspinous ligaments; (3) the ligamentum flavum (the tip is then within the epidural space); (4) the dura. On passing through the dura, the bevel will lie within the subarachnoid

FIG. 39 Spinal anesthesia

B. Posture for spinal tap in lateral position. Note patient at edge of bed, with spine well flexed and pelvis and shoulders vertical.

space. It is important that the entire lumen of the bevel should be so placed that it should not lie halfway in and halfway out. The stylet is then withdrawn and when a free flow of cerebrospinal fluid ensues, the spinal analgesic is injected. The iodine is then removed with alcohol, the back dried, and the patient's position gently changed in order to attain the correct level of anesthesia. It is unwise to test for an anesthetic level too vigorously, if at all, as this makes the patient apprehensive. Thereafter, careful observations should be made of the patient's clinical condition until his recovery.

Oxygen should be administered if there is respiratory depression, while a sleeping dose of some agent may be thought advisable.

Precautions.—At all times, during any form of conduction analgesia, an anesthetic machine, with which to administer oxygen, should be at hand. Likewise, endotracheal tubes and a laryngoscope should be readily available in order to efficiently oxygenate either a subject who has received a relative overdose of anesthetic agent, from too rapid absorption, or one in whom spinal or epidural analgesia has paralyzed the phrenic nerves. Pentothal should be prepared and ready for use in order to control the convulsions which may result from a relative overdose.

Advantages of Spinal Analgesia:

- 1 Excellent muscular relaxation is provided
- 2 There is little disturbance of metabolism
- 3 The inhalation of irritating drugs is unnecessary so that the patient does not suffer from postanesthetic nausea and prolonged sleep
- 4 The use of the electrocautery and other electric appliances is permissible

Disadvantages of Spinal Analgesia

- 1 It is difficult to control
- 2 Its duration is variable and uncertain
- 3 Technical difficulties may result in absence of analgesia
- 4 Motor analgesia may ascend to high levels. If this occurs, respiration can and should be aided and adequate oxygen provided
- 5 Severe circulatory collapse may follow the administration of a spinal analgesic

6. Consciousness during operation is not desirable in some cases.

7. Retching may follow traction on the viscera, since the vagal pathways are not blocked.

8. Postoperative neurologic complications may follow spinal analgesia. The most common of these is headache, the most serious ones, though uncommon, are of disastrous nature.

Regional analgesia is becoming more popular as techniques improve. This is true not only in providing analgesia for surgery but, perhaps of more importance, in the various diagnostic and therapeutic procedures related to vasospasm, causalgia, etc.

Reference should be made to standard texts for further details about conduction analgesia.

ANESTHESIA AND SURGICAL BLOOD LOSS

Anesthesia can have a profound effect on surgical hemorrhage. Poor anesthetic technique may double the amount of blood lost during operation, whereas good tranquil anesthesia, with attention to a few simple rules, can effect great economy in blood as well as the surgeon's time and effort during a difficult dissection. "A pint of blood saved is worth two in the bank," is nearly true, quantitatively as well as qualitatively, when one remembers that every 500 ml. of bank blood is made up of 150 ml. of dextrose citrate solution and only 350 ml. of whole donor blood.

Blood loss from a surgical incision is dependent on two factors, the size of the cut vessels in the incision and the pressure of the blood in those vessels. Measures to diminish blood loss are based on reducing one or the other of these factors. (See Chapter 4)

Controlled Hypotension

There are many situations where injection of vasoconstrictor solutions is undesirable or dangerous; for example, in the neighborhood of malignant tissue, where injection techniques may spread the disease further; in these circumstances, attention is directed to reducing the hydrostatic level of pressure in the vessels of the operative site. An obvious and simple method is depression of local pressure by elevation of the part; for example, the use of a

head-down tilt during operations for varicose veins or the placement of the arm on a raised support in operations on the upper limb. Lord Lister pointed this out many years ago, but succeeding generations forget and have to re-discover this simple maneuver.

In recent years a great many papers have appeared on the subject of controlled arterial hypotension.

Before inducing hypotension as an aid to any particular operation, the morbidity of this measure should be considered. In patients in whom there is pre-existing coronary disease, cerebral arteriosclerosis, or renal inefficiency, the marked fall in blood pressure may prove fatal.

It is argued that whatever the initial mean arterial pressure, by the time the blood reaches

the vascular tone is in a state of vasodilatation. In oligemic shock, when compensatory vasoconstriction exists, blood supply to vital organs may be inadequate at these levels.

Curiously enough, while so much attention has been focused on the arterial pressure, little thought appears to have been given to the venous side of the circulation. This omission is the cause of some inconsistency in the published work on arterial hypotension, because from the standpoint of blood loss, the venous pressure is probably much more important than the arterial pressure, since it is a more labile factor and more directly affected by changes in respiratory resistance.

Changes of intrathoracic pressure are transmitted directly to the great veins and from there via the intervertebral foramina to the valveless extradural plexuses, which equalize

Fig. 60 - Changes of mean blood pressure across the arterial and capillary beds under normal conditions (on left) and with raised airway pressure (After Bromage)

the capillary bed, peripheral resistance has reduced the mean pressure to about 32 mm Hg, and this pressure of 32 mm Hg is the only one of importance for tissue perfusion in a resting individual; higher pressures are merely additional supplies in hand for the changing needs of a conscious dynamic organism. Therefore, provided peripheral resistance is abolished by removal of sympathetic tone, and provided the blood volume remains constant, a mean arterial pressure slightly in excess of 32 mm Hg should be sufficient. However, this argument fails to consider the needs of secondary capillary circulations such as are found in the liver and pituitary (pituitary-hypophyseal portal system), and for these systems mean pressures somewhat in excess of 32 mm Hg are probably necessary. In practice, mean pressures in the region of 50-60 mm Hg appear to be safe (i.e., 75/40-90/50 mm Hg), provided

venous pressures all over the body. Thus, during coughing or straining or partial obstruction of the airway, the venous pressure throughout the body rises, and in extreme cases blood flow in the capillary bed may be halted or actually reversed. In the conscious subject, venous pressures follow closely upon changes of airway pressure. But, under anesthesia, venomotor reflexes appear to be exaggerated, so that instead of returning to normal after a bout of coughing, a raised venous pressure persists for 20-30 minutes, and during this time blood loss from capillaries and venules is greatly increased.

Translated into practical terms, this means that for optimal surgical conditions anesthesia must be entirely tranquil at all times. There must be no coughing or straining or increased airway resistance from the moment of induction onward.

Completely tranquil anesthesia, with the patient postured so that the operative site is at the highest level, goes far to provide a relatively dry surgical field. Where an extra reduction of bleeding is required, as in neurosurgery, arterial hypotension is added to this background of tranquility.

Arterial Hypotension

Arteriotomy.—The circulating blood volume is temporarily reduced by removing up to 1,200 ml. of blood from a major artery, usually the radial, and the blood is reinjected at the end of operation. This procedure induces a state of temporary oligemic shock with arterial hypotension and vasoconstriction. Although very effective for neurosurgery, the accompanying vasoconstriction jeopardizes the blood supply to parenchymatous organs and makes it a dangerous method.

Spinal Blockade.—High subarachnoid or extradural spinal block produces a temporary preganglionic sympathectomy, with accompanying vasodilatation and fall of arterial pressure. The systolic level is controlled by posture and raised by vasopressor drugs if necessary.

Ganglionic Blockade.—Some drugs of the methonium group, pentamethonium and hexamethonium, produce ganglionic blockade which lasts about 45 minutes when given intravenously. A thiophanium derivative, Arfonad, is shorter acting and more controllable, and this is administered by continuous intravenous infusion. Drugs with less clear-cut actions may also be used. For example, chlorpromazine has a combined adrenergic and ganglion-blocking effect, as well as producing depression of the central nervous system, this may be useful for intraocular operations where a low intraocular tension combined with prolonged postoperative sedation is desirable.

HYPOTHERMIA

The state of hypothermia appears to have been introduced by Simpson and Hering of Edinburgh, who in 1905 lowered the temperature of cats for experimental purposes. They described the condition produced as being one of artificial hibernation and realized that in this state metabolism was depressed.

This theory was not utilized clinically until Temple Fay incorporated it in the treatment of malignant tumors. It is interesting to note that since then, cooling has been shown to depress hypophyseal function. The regime of cooling patients was later tried in the treatment of schizophrenia.

The first really useful clinical application of hypothermia was its introduction to combat the hyperthermia that may follow major surgery in children and infants. Since then research work has been undertaken in many centers, some of the most important contributions coming from Bigelow of Toronto.

Universal employment of hypothermia has followed the postulation that in this state metabolism is reduced; the oxygen consumption of the brain is diminished by approximately 50% at a temperature of 30° C. The temperature of 30° C. is regarded in many centers as being the optimum for cooling purposes.

Advantage can be taken of hypothermia in certain types of surgery in which the blood supply, and therefore oxygenation, of the brain may be interfered with for periods which previously would have been considered impossible, without being either lethal or grossly morbid. Use of this principle can also be made under other circumstances, such as closed head injuries, when it may be thought beneficial to reduce brain metabolism and incidentally to relieve brain edema.

Physiologic Responses to Hypothermia

The natural response to cold is the shiver reflex. If shivering is allowed to occur when the body is cooled, the initial responses are entirely different from those found in a subject who is prevented from shivering by anesthesia or a muscle-depressant drug. If shivering is allowed to occur, oxygen consumption is greatly increased, the blood pressure and pulse rate rise, and the cardiac output is grossly augmented. In similar fashion, respiratory rate, depth, and the minute volume are all elevated.

Once a temperature of 30° C. is reached, the subject is almost completely anesthetized by the cold; he lies as if in a trance, requiring only nitrous oxide and a bare minimum of other anesthetic agents before surgery is undertaken. Further discussion of the body's re-

sponses refers to those conditions that occur when shivering has been prevented or controlled.

Cardiovascular System.—There is a reduction in blood pressure and pulse pressure while at the same time the pulse rate is lowered. Below a temperature of 30°C , myocardial irritability is increased as demonstrated by the incidence of cardiac irregularity, the frequency of which increases with decreasing body temperature. The advent of auricular fibrillation, which is not uncommon, though innocuous in itself, should be regarded as a sign that the pacemaker is wandering and that keen observation and great care be exercised. When the temperature is reduced to between $28^{\circ}\text{--}26^{\circ}\text{C}$, irregularities may herald ventricular fibrillation.

However, at this temperature ventricular fibrillation may occur spontaneously, or it may follow a period of marked bradycardia accompanied by extrasystoles.

The activity of the myocardium in the cooled patient or experimental animal shows specific electric changes which are reversible. Ventricular fibrillation is most frequently encountered in operations that necessitate the handling of the heart. Many factors besides actual trauma have been held responsible for this ever-present hazard of hypothermia. Anoxia, acidosis, hyperkalemia, and acetylcholine metabolism have each in turn been incriminated. There is therefore no certain knowledge as to why this complication occurs.

Fig. 61—Chart showing vital signs during a craniotomy under hypothermia

when cooling the mammal Burton and Edholm record that the heart of the European marmot can easily be made to fibrillate by cold during its active stage, whereas the heart of a similar animal when hibernating will not so respond

Respiratory System.—The rate and depth of respiration increase in the early stages of cooling and then they decrease, the oxygen consumption, after an initial rise, diminishes. This diminution in oxygen consumption succeeds the fall in minute volume. The carbon-dioxide content of the alveolar air is decreased, but the solubility of carbon dioxide is increased, and the arterial content rises. The increased plasma carbon-dioxide tension counterbalances the swing to the left of the oxygen dissociation curve brought about by cold. When the temperature is lowered, the respiratory center becomes less active and the carotid body relatively more so.

Blood Gases.—The arterial oxygen concentration is well maintained with normal ventilation. There is no evidence that breathing an atmosphere enriched with oxygen is of advantage. The percentage of dissolved oxygen increases with the lowering of temperature. The plasma carbon-dioxide level tends to rise and the pH to fall very gradually but progressively.

Blood.—The hematocrit is elevated, and the viscosity of the blood is increased. There is therefore a loss of plasma for which as yet there is no accounting. The bleeding time may be increased, and the coagulation process may in some way be affected.

Kidneys.—The renal output varies with the blood pressure and the effect of the antidiuretic hormone. No pathologic changes have been reported except those by Knocker. In cooled dogs she found changes in the kidneys analogous to those found in death from anoxia.

Liver.—During the induction of hypothermia, glycogen is synthesized. Thereafter, the blood sugar level rises. This fact seems first to have been pointed out by Claude Bernard and rediscovered in the Dachau concentration camp experiments. Knocker found changes in the liver similar to those she found in the kidney. When hypothermia is established, the many functions of the liver are slowed down;

it is therefore important to modify the dose of all drugs given under these circumstances.

Biochemical Changes.—When patients are kept cool for a considerable period, the levels of potassium, sodium, and chloride tend to vary. They therefore need careful watching and correction by appropriate infusions. Enzyme activity is greatly modified during hypothermia.

Clinical Hypothermia

The Use of Drugs in Hypothermia.—Drugs such as chlorpromazine or Hydergine, by virtue of their antiadrenergic action, cause vasodilatation and therefore facilitate the production of hypothermia. Some of the other actions of the drugs may also be of advantage during the induction and maintenance of hypothermia. The anticholinergic and antihistaminic efforts of drugs such as Phenergan and the sedative effect of Demerol may be incorporated in the medication which precedes hypothermia. Such a mixture prevents shivering, induces anesthesia, and expedites the cooling by the vasodilatation produced. Should shivering occur under these circumstances it can readily be controlled by minimal doses of Pentothal. The mixture of chlorpromazine, Phenergan, and Demerol or similar drugs was introduced by Laborit and Huguenard as the lytic cocktail. This mixture alone is capable of producing a type of anesthesia, this procedure being termed potentiater anesthesia. These drugs alone do not produce hypothermia. It was originally thought, neither is there valid evidence to support the claim that their use prevents the occurrence of cardiac irregularities when they are used in association with physical cooling.

By virtue of the fact that these drugs depress autonomic nerve transmission and therefore autonomic nerve responses, it has been claimed that suitable mixtures may be used advantageously in the management of shock. This theory has been given trial, but as yet it has not been universally accepted.

Indications for the Use of Hypothermia

Short Term.—This has been advocated for cardiac surgery when the circulation will be interrupted, also for certain neurosurgical operations such as cerebral aneurysm or vascular

ANESTHESIA

tumor, when the circulation of the brain may be temporarily cut off. It may find a place in surgery of the major ablative or extirpative type.

Long Term.—This is carried out in some centers in the treatment of certain cases of closed head injury, ruptured cerebral aneurysm, encephalitis, and hyperthermic poliomyelitis. There are some who advocate its use in the treatment of tetanus and of certain hyperthermic conditions.

Methods of Cooling

There are the following methods: (1) surface cooling, (2) extracorporeal cooling, and (3) cavity irrigation. The details of these methods must be studied elsewhere. Surface cooling appears suited to neurosurgical cases, while the extracorporeal method, in which blood is artificially by-passed through a cooling and possibly also oxygenating apparatus and then returned to another vessel, is more adaptable to heart surgery.

Once a patient has been cooled, great care has to be taken to make accurate observations. The temperature should be recorded in the esophagus distal to the bifurcation of the trachea and also in the rectum. It should be noted that when a subject is cooled, there is a continuous drift downward of a further 2° C, after active measures of cooling have been discontinued. This is because the muscle bed of the body acts as a reservoir of cold. It should also be noted that there may be a difference of up to about 4° C between the temperatures recorded in the esophagus and rectum. The former is that taken as being indicative of the heart temperature. Electrocardiographic studies must constantly be made and the blood pH checked from time to time.

When hypothermia procedures are used, there must always be at hand a defibrillator which has been previously checked and found in working order.

During the long term cases, monitoring must also include daily studies of hematology and biochemical importance as well as urinary secretion. Dependent upon these is the quantity and quality of the intravenous therapy which

also must contain additional vitamins. Great care in these long-term cases must be taken to preserve a perfect airway, avoid infection, and prevent shivering.

CHOICE OF ANESTHETIC

The anesthetic selected should provide the patient with a comfortable and not too unpleasant interlude and the surgeon with nearly ideal operating conditions as possible without increasing the risk to the patient.

The patient may have prejudices regarding anesthesia, and his wishes must be given consideration; however, his physical status and the nature of the contemplated surgery are the more important factors. The anesthetic drugs selected should be such that their action does not adversely affect other complicating diseases. For example, patients with respiratory infections are usually safer if not given an inhalation agent, and patients in shock should not receive a spinal anesthetic or straight Pentothal anesthesia. Shocked patients should, if possible, not be anesthetized until the state of shock has been brought under control. If, owing to the nature of the condition, the patient must be anesthetized at once, this should not be undertaken in a manner that might interfere with the patient's compensatory reflexes.

The anesthetist should know the surgeon's preferences, how much relaxation he will require, and how long he is likely to take to perform the operation. For most intra-abdominal operations, it is necessary to provide a marked degree of relaxation, whereas, for example, in the case of a niastectomy, a less potent anesthetic agent or a lighter level of anesthesia suffices.

COMPLICATIONS FOLLOWING ANESTHESIA

It is not possible here to give a detailed account of all the complications which may follow anesthesia. As in the former paragraph, the aim of this brief outline is to convey fundamental ideas. It may be stated that the vast majority of the sequelae referable to anesthesia are preventable. Thought, therefore, must be given to possible deleterious effects.

when agents are selected and procedures performed. Each system must be mentally reviewed: will this cause a fall in blood pressure? If so, will it be harmful? Is this likely to cause atelectasis? Will this ensure that the cough reflex is regained soon after the operation? Will this produce respiratory acidosis? If such and such be done, certain complications might occur; are the benefits that it confers worth a possible risk? Can the operative position produce ill aftereffects? Has due caution been paid to the prevention of nerve palsies, cautery burns, pressure sores, and explosions?

RESUSCITATION AND OXYGEN THERAPY

Reference is here made to the sections elsewhere in this book on shock, transfusions, infusions, and cortisone, as the anesthetist must be as familiar as any one with these subjects. Details concerning the care and treatment of a patient in shock, the optimum time for operation, the anesthetic to be given in these circumstances, and the postoperative care are integral parts of his work. Indeed, in time of war or emergency, he may be solely responsible for them. At all times the treatment must be based upon what is known of the underlying physiopathology. Incorrect treatment may aggravate the condition.

The use of oxygen may be of benefit, it may produce no response or if not used correctly, it may have ill effects which might even prove fatal. The methods of administration should be carefully considered before oxygen is used, and its use should be supervised. It should not be left to someone without knowledge, for under such circumstances administration might be dangerous, while at the best it would be wasteful.

Normal blood of a patient breathing room air contains 20 ml oxygen per 100 ml. Of this, 19.7 ml % is carried as oxyhemoglobin, producing 95% saturation, and 0.3 ml % is in solution in the plasma. When 100% oxygen is given, the hemoglobin becomes 100% saturated, an increase of 5%, and the concentration in the plasma rises to 2.3 ml %. This gives a total content of 23.5 ml/100 ml blood, or a percentage increase of over 15%.

Advantage may at times be taken of the physical and pharmacologic properties of helium and carbon dioxide. The former, though inert in itself, lowers the density of inhaled gases; the latter is the most powerful stimulant to the respiratory center. Oxygen under a pressure of 4 ml water during expiration may be valuable in re-establishing the normal transalveolar tensions in a case of pulmonary edema.

The necessary humidity of gases for inhalation should be remembered and the benefits of high humidity under certain circumstances known, while familiarity with the nebulization of drugs, their mucolytic and bronchodilator nature, should be gained.

THE POSTOPERATIVE RECOVERY ROOM

There are certain principles of importance to both anesthetist and surgeon during the stage of early postoperative care.

1. When patients leave the operating room, with few exceptions, they should have regained their cough reflex.

2. Patients may have to be handled; this should be done in the most gentle manner possible. The sympathetic control of blood vessels and the automatic vascular reflexes may still be depressed; hence roughness at this stage may precipitate a fall in blood pressure. Such a fall has been known to be fatal.

3. An unobstructed airway must be obtained. To ensure this, suction must be at hand; if possible, there should be alternative facilities to secure it, lest one method break down.

4. Posture is of considerable importance. The unconscious patient should be placed in the lateral or post-tonsillectomy position, so that ingress of foreign material into the trachea is avoided. Thereafter, the patient can be turned every hour to ensure equal ventilation of both lungs. This position is feasible after most operations. The beds should be of a type that can rapidly have the foot elevated. Specially designed recovery-room stretchers and beds are now available.

5. Equipment for oxygen therapy should be readily available.

22-25

6. Intravenous therapy will require special supervision, while the facilities of the blood bank should be readily available

7 Gastric and other suction, drainage tube and dressings, bladder irrigations, casts and such like must constantly be watched.

■ Pain is relieved in the recovery room according to the individual's needs and not by routine prescription of drugs that might prove ill suited

9 All therapy, observations, and records of the vital functions should be checked. The ideal system would be to have a chart continuous with the anesthetic chart, so that the whole procedure can readily be reviewed

10 Physiotherapy directed toward the minimization of pulmonary and venous complications may be initiated

11 There should be readily available all equipment that might possibly be needed, including the following

a Mouth gag, mouth props, a variety of airways to suit all ages, metal suction tips and rubber or plastic suction catheter, a laryngoscope with a variety of blades, endotracheal catheter, and bronchoscopes with spare bulbs

b All equipment necessary to support the circulation, such as intravenous equipment and solutions, cutdown sets, and intravenous stands

c Equipment for assisting or controlling respiration, such as an anesthetic machine with which to give oxygen, and some form of resuscitator

d Consideration given to the equipment necessary for looking after special cases, such as laryngectomies and hypothermic procedures

e Emergency equipment and personnel in the event of cardiac arrest.

f Emergency bell and electric clock with sweep hand

12 A variety of drugs should be readily available, such as (a) narcotics and their antagonists, (b) atropine and hyoscine, (c) barbiturates and their antagonists, (d) vaso-pressors, (e) analeptics, (f) anticoagulant drugs, (g) antihemorrhagic drugs, (h) antihistaminic drugs, (i) antibiotics, (j) ATS, insulin, and hydrocortisone

RECORDS

The charting of information should never replace the care and attention needed to give an anesthetic properly, but there should be time to record the reactions of the vital functions and the use of various agents, drugs, and infusions. Such observations may be of help during the postoperative period, and, if accurate, their value for analytical purposes may be great. In this day and age their medico-legal significance has greatly increased

EXPLOSIVE HAZARDS

The anesthetist should always be aware of the possibility of an explosion, which necessitates a source of ignition and an inflammable mixture. The former may come from (a) a spark from electric equipment as exemplified by endoscopic instruments, electric cautery, switches, plugs, light lamps, or faulty wiring, (b) an open flame or burning instrument; (c) static electricity

It has been stated that switches and plugs in an operating room should be of the explosion-proof variety, unless they are placed 5 feet above the ground. All endoscopic equipment should be carefully checked and wiring faults eliminated. Only under special circumstances should the cautery or similar instrument be used in the presence of inflammable gases or vapors; such circumstances include proper ventilation, the use of a high humidity atmosphere, and the aspiration of the exhaled gas mixtures. Every effort should be used to reduce the chance of static sparks occurring. These include the use of cotton clothes and coverings for patient and personnel, the use of conducting floors, and the grounding of all equipment and personnel.

In order entirely to eliminate the possibility of explosion, those techniques and agents must be used in which inflammable gases, vapors, or liquids are avoided. Such include all forms of conduction analgesia, barbiturate anesthesia, nitrous oxide and oxygen mixtures, trichlorethylene analgesia, intravenous narcotics, and relaxing agents or combinations of them. To this list may be added one of the oldest anesthetic agents, chloroform, and one of the most recent, fluothane.

FINAL REMARKS

There has been little discussion of anesthesia for specific operations, for patients suffering from various disorders, and for those of different age groups. The choice of anesthetic does not depend so much upon the agents as upon the manner of their administration. There are exceptions to this statement. The part-time or learning anesthetist should perfect one technique at a time. He should avoid using agents with which he is not familiar even if they are theoretically the agents of choice.

In dealing with children the scaled-down anatomy and modified physiology must be considered. With the aged and with patients who are suffering from such conditions as heart disease, pulmonary insufficiency, and glandular disorders, different factors must be noted and appropriate action taken.

Chapter 9

Surgical Technique

David W. MacKenzie, Jr., MD, and Mary G. Warnock, RN.

PRINCIPLES OF WOUND HEALING

Problems relative to the healing of wounds, acquired because of trauma or surgical intervention, are of fundamental importance. A surgeon's interest in and ability to cope with such problems are an accurate measure of his technical skill. Failure to appreciate the principles involved, which are few in number and entirely self-evident, produces disastrous results. An understanding of the natural forces of healing, of the sequence and timing of events in the process of repair, and of factors which, on the one hand, expedite and, on the other, retard this process is essential to good surgery.

Wounds are classified as follows:

1. Abrasions
2. Contusions
3. Lacerations, with or without contusion, abrasion, or loss of substance
4. Burns
5. Incised wounds, clean, contaminated, or infected

The first two categories will not be considered at present. The third, concerning traumatic lacerations and associated complications, will be covered under wound excision and débridement later in this section.

The healing process in surgically incised wounds is precisely the same as that in traumatic lacerations, except that it is usually

quicker, with less deformity and loss of function. The rate of healing and the ultimate anatomic and physiologic results obtained depend to a very great extent upon the technique of the operator. Other contributing factors will be dealt with subsequently.

Surgical dissection may be *sharp* or *blunt*. Sharp dissection is carried out with the blade of the knife, blunt dissection, with scissors, the handle of the knife, any suitable instrument, a gauze sponge, or the surgeon's finger. For the most part, sharp dissection is preferable. It effects clean exposure and creates relatively little trauma. Blunt dissection is employed as a minor complement to sharp dissection. Cleavage planes yield nicely to strokes of the blade, together with an occasional gentle push by the handle of the knife. Forceful blunt dissection is never to be condoned. It tears and contuses the tissues, opens up potential dead spaces far beyond the required field, and predisposes to hemorrhage and infection.

Control of hemorrhage is essential. A surgeon's efficiency may be judged by the dryness and neatness of his wound. It is impossible to operate effectively, and dangerous to attempt to do so, in the presence of uncontrolled bleeding. Whenever possible, vessels should be seen and accurately clamped with finely pointed hemostats before being cut. Together with the vessel, the clamp should crush little or none of the adjacent tissues. Ligation of large bites of tissue is to be de-

plored. Ligature by transfixion is recommended for all large vessels and for some small ones, when it is difficult to stabilize the knot. Transfixion also makes possible the use of more delicate suture material than would be required otherwise. Within reason, the fewer and less bulky the ligatures, the better the healing of the wound. Experience teaches which smaller vessels must be tied and which may be left to contract spontaneously and thrombose. Hematoma formation in a clean incision, besides delaying wound healing and predisposing to infection, indicates poor surgical technique.

various types of catgut, plain or chromicized; the latter, such materials as silk, cotton, stainless steel, silver, and numerous plastics. They are available in various sizes, from the extremely fine to the very coarse.

The choice of suture material is governed by the nature of the operation and the presence of contamination or infection. It is also influenced by the individual preference of the surgeon and by the facilities which are available to him.

Operations are classified as clean, contaminated, and infected. Elective hernia repairs,

Fig 63—Methods of vascular ligation. The first diagram represents the common manner of simple ligation. The others show various stages and types of ligation by transfixion. These last have been modified from those of Halsted which appear in his monograph on *The Use of Silk in Surgery*, published by the Welch Bibliophylic Society in 1939.

Adequate reconstruction of a surgical incision implies accurate apposition of the various fascial planes without tension, obliteration of dead spaces, and absolute hemostasis. The tensile strength of the sutures need be no greater than that of the tissues they are designed to secure. The sutures should take small bites and must not be tied so tightly as to cause necrosis of the tissues which they compress. Bulky suture material of any sort complicates wound healing. The less foreign material present in an incision, the better. Each suture, therefore, should be cut as close to its knot as is compatible with security.

Suture materials are classified as *absorbable* or *nonabsorbable*. The former group includes

mastectomies, and thyroidectomies are examples of clean operations. Interval appendectomies and cholecystectomies may be minimally contaminated. Stomach and bowel resections are contaminated. Cases dealing with acute or subacute inflammatory lesions are said to be infected.

A clean wound may be repaired with either absorbable or nonabsorbable sutures. In a contaminated case, which becomes infected, nonabsorbable sutures predispose to sinus formation, except in situations where they are rapidly sealed off as occurs in the seromuscular layer of intestinal anastomosis. Stainless steel wire is the nonabsorbable suture material least likely to cause sinus formation complicating wound

infection. However, nonabsorbable sutures of any sort must not be buried in the presence of infection.

The first significant report on the use of silk in surgery was published in 1888 by Theodor Kocher, who noted that wounds repaired with silk became infected much less frequently than those repaired with catgut. Kocher's influence and his own ambition to perfect a technique of clean wound repair led Halsted to adopt silk. His meticulous personal use of this medium and his instruction of others soon developed, at the Johns Hopkins Hospital, a school of surgery which, on this continent, remained for many years unique. George Heuer's monograph* on Halsted's life and work, which was published on the occasion of the centennial of the birth of this great teacher-surgeon, contains the comment here quoted, to inform the student of the qualities of the man whose influence on North American surgery may never be surpassed: "During his Baltimore period he was the exemplification of the slow, careful, painstaking surgeon who is concerned with the patient's safety, not with his own brilliancy. He was aware then, as most of us now are, that safe and successful surgery is the result, not of a rapid and dexterously performed operation, but of a combination of factors which includes the routine preliminary preparation of the patient, selected and well-administered anesthesia, perfect aseptic surgical technique, the gentle handling of all tissues exposed, the careful avoidance of injury to all structures not involved in the operative procedure, and the use of fine delicate instruments and suture material of fine silk in the control of hemorrhage and the closure of the wound. No one appreciated more keenly than he that the safety of the patient and the success of an operation can be jeopardized by a faulty anesthetic, by infection, by injury to an important structure, or by failure of proper wound healing."

Yet silk has never received general acclaim, despite the experimental and clinical evidence

in its favor provided by many distinguished surgeons since Halsted's time. This is not difficult to explain. Silk demands the utmost in aseptic technique and in painstaking surgical judgment and skill. The requirements of ideal wound healing must be appreciated and fulfilled with precision: minimal trauma, rigorous hemostasis, and anatomic reconstruction without tension. As Halsted remarked, "In the hand of a bad technician silk is disastrous."

While there is no doubt that, under identical conditions, the healing process in a "silk" wound exhibits considerably less inflammatory reaction than in a "catgut" wound, the gross difference is not nearly so marked when catgut of comparable delicacy is used with the same precautions against trauma, tension, and hemorrhage as those required by the use of silk.

The work of Howes and others has dissipated the illusion of catgut allergy, which was formerly blamed for the occasional disruption of wounds repaired with absorbable sutures. If the contributory factors of tissue devitalization and increased tension are present in sufficient degree, a wound will disrupt as readily through sutures of catgut, silk, or steel. It seems reasonable to conclude that a careful and well-trained surgeon, working under suitable conditions, will use silk (or other equally inert and delicate material) in clean wounds; but that, when in any doubt regarding the presence of contamination or infection, he will rely on fine catgut handled in the same manner.

WOUND EXCISION

Wound excision consists in the systematic removal of all devitalized or grossly contaminated tissue from a recently inflicted wound. It attempts to convert a contaminated and potentially infected lesion into one that is relatively clean. Depending upon the nature and site of the wound and the degree of its contamination, the time factor is somewhat elastic. Early, adequate excision of a contaminated wound is usually followed by uncomplicated healing. Wound excision following bacterial proliferation is dangerous, because it removes natural barriers to spreading infection.

*Heuer, G. W.: Bull. Johns Hopkins Hosp. (suppl.) 20: 50, 1932.

Generally speaking, it is safe to perform wound excision within 12 hours of injury. In selected cases, minimally contaminated and presenting no sign of infection, the safe period may be extended a few hours.

The excision of a wound is performed in layers from without inward. Dead spaces are eliminated and hemostasis secured. Adequate drainage is established. The wound is enlarged, depending upon the extent of its penetration, by suitably placed incisions, which may increase its greatest diameter four to six times. Contused skin edges are cut away with a scalpel. As little healthy skin as possible is sacrificed in this procedure. Subcutaneous fat that is flecked with foreign material, severely contused, or infiltrated with blood is then removed. Deep fascial planes, which might prevent adequate drainage, are incised, preferably parallel to their fibers, but, when necessary, transversely. The viability of traumatized muscle is determined by its ability to contract when compressed by forceps. When in doubt, it is safer to excise more than less, for ischemic muscle is an ideal medium for gas gangrene infection. In compound fractures, only those bone fragments which are completely separated from periosteum and muscle should be removed.

When practical, it is advisable to change gloves and dissection instruments after the skin layer has been excised. Some advocate voluminous saline irrigation of the wound with each succeeding step of excision. We feel that irrigation may at times be helpful, but that, in excess, it obscures the extent of contamination and may, in fact, spread potentially infected material beyond the natural confines of the wound. We prefer not to irrigate wounds that are excisable.

The excised wound is lightly filled, not packed, with dry, fluffed dressing gauze, after its walls have been covered with a single layer of finely meshed (bandage), gauze or silk, of which the interstices are small enough to prevent the inward growth of granulation tissue. This dressing is secured by an elastic bandage, and the lesion is immobilized by splinting or a plaster cast.

In excisable wounds, we feel that topical chemotherapy, applied as a thin film of finely particulate powder, is indicated. A wide-spectrum antibiotic is recommended for this purpose.

The term *débridement*, as applied to wounds, is by some considered synonymous with excision. We prefer, however, to confine its use to describe the management of wounds which are unsuitable for excision. In such cases, the lapse of time between injury and operation is commonly much longer than the safe period for excision. There is gross tissue devitalization, and suppuration is evident. Infection is established to a moderate or marked degree.

The aims of *débridement* are to relieve tension, to remove such necrotic tissue and foreign material as is readily accessible, without disrupting natural barriers to spreading infection, and to effect adequate drainage of all regions of the wound. Tension is diminished by incision of confining fascial planes. Loosely adherent slough is clipped away. Foreign bodies are removed, when this may be accomplished without extensive exploration. Dead spaces are unroofed and the defect is filled with dry, fluffed gauze dressings. Counter-drainage is established when indicated. It is doubtful that topical chemotherapy of any sort is effective in such wounds or that their irrigation with antiseptic solutions speeds the healing process. Most important is their complete immobilization, preferably in highly absorbent plaster-of-Paris casts. Infrequent dressings are definitely indicated. Each change of dressing inflicts trauma, delays healing, and increases the incidence of cross-infection. These facts were established by Trueta during the Spanish Civil War and have stood the test of time since then.

CLOSURE OF ACCIDENTAL WOUNDS

Small, superficial, cleanly incised wounds within 12 hours of infliction and following excision of grossly contaminated fat, fascia, and devitalized skin may be closed safely by *primary suture*. Larger, more deeply penetrating wounds, though recent, are better treated by

excision and closed by *delayed primary suture* after 48-72 hours or by *secondary suture* after 7-14 days or longer. In such cases the optimum time for closure occurs when the entire defect is lined by healthy granulation tissue, when no dead space remains, and when all slough has separated.

Wounds that, for the reasons mentioned, require débridement rather than excision may be closed by secondary suture after an interval of several weeks. Because of excessive loss of substance, however, they often require one or the other type of definitive plastic repair.

SUPERVISION OF WOUND HEALING

The incidence of wound healing complications is inversely proportional to the surgeon's technical ability and the efficiency of his operating team. It is obvious, therefore, that such complications should be scrupulously recorded and subjected to frequent review. By means of this information, errors in surgical judgment and technique, in sterilization procedures, etc. are detected and eliminated without delay. Infection, nutritional deficiencies, metabolic disorders, blood dyscrasias, and numerous other factors impede the normal process of repair to such an extent that the more serious complications of wound healing are, at times, inevitable. To record only such major catastrophes is of little value. The picture must be complete: either a surgical incision heals cleanly by primary union or it does not. If the slightest complication occurs, it should be noted in the progress report and discharge summary of the case.

To properly assess the quality of wound healing, the type of case—clean, contaminated, or infected—must be stated, suture materials and drainage devices noted, and healing summarized as follows: (1) healed cleanly by primary union; (2) stitch abscess; (3) hematoma; (4) trivial infection; (5) serious infection; (6) wound disruption.

An accurate statistical record of wound healing, presented as an annual report, will clearly demonstrate technical improvement or the reverse.

SURGICAL STERILIZATION

Surgical sterilization implies absolute destruction of bacteria. It is accomplished by physical or chemical processes: by immersion in boiling water for at least 10 minutes; by autoclaving at 18 pounds pressure (25¹⁰ F.) for varying periods, depending upon the article to be sterilized; by dry heat in the hot air oven, or by chemical reagents, such as ethyl alcohol (70%), oxycyanide of mercury (1:1,000), biniodide of mercury, or numerous other antiseptics.

Routine procedures are devised for the maintenance and sterilization of all types of surgical equipment. A few of the commoner methods should be mentioned. Packaged dry goods, granite ware, rubber goods (including drainage material), silk sutures, brushes, and glassware are autoclaved for 30 minutes, rubber gloves for 15 minutes, and instruments for 10-20 minutes. Articles that may be damaged by intense heat are immersed in appropriate antiseptic solutions for varying periods.

SCRUBBING FOR OPERATIONS

It is impossible to sterilize completely the hands of the operating team. Numerous reagents, because of their bactericidal and detergent properties, reduce bacterial flora to a minimum, but surgical sterilization is never accomplished. Systematic scrubbing for 10 minutes with a bland, superfatted soap, and brush of not too coarse texture, followed by 1 minute's immersion of the rinsed hands and forearms in a trough of mild antiseptic (aqueous Zephiran, 1:1,000) is an effective routine. Frequent scrubbing facilitates cleaning. Adjuvant detergents and antiseptics may reduce scrubbing time to a minimum of 3 minutes.

The following points concerning scrub-up must be emphasized:

1. There must not be any infection of the skin or break in skin continuity (abrasion or laceration) of the hands or forearms.
2. The nails should be clean, smooth, and pared short.
3. The scrub-up zone should include the elbows.

SCRUBBING FOR OPERATIONS

Fig. 61—Application of rubber gloves
1, Method of removing powder package from glove cuff
2 and 3, Method of putting on gloves, hand to hand and glove to-glove technique.
4, Method of rolling glove cuff over cuff of gown

PREPARATION OF THE OPERATIVE FIELD

The night before operation, the area is cleansed with green soap and carefully shaved far beyond the limits of incision. In the operating room, further cleansing is carried out with alcohol and ether, and an antiseptic solution is applied in systematic strokes from the center of the field to its periphery. Contaminated zones are painted last

SURGICAL INCISIONS

An incision is designed primarily to afford the best possible exposure of the lesion in question, with minimal retraction of adjacent structures. It should, for cosmetic reasons, parallel the natural creases of the skin. Its course should be at a right angle to the minimal distracting forces in the area. It should avoid compromising major nerves and blood vessels and, when practical, divide fascial apo-

Fig 65—Commoner breaks in aseptic technique 1, Second assistant's left arm outside sterile field 2, Inadequately draped anesthesia screen 3, First assistant improperly masked 4, Instrument nurse's hair uncovered by cap 5, First assistant reaching behind instrument nurse 6, Hustle nurse's uniform touching sterile hand basin 7, Surgeon's hand below level of sterile field 8, Surgeon's cuff outside glove 9, Second assistant's retractor outside sterile field

For orthopedic operations it is customary to supplement the above procedure by one or more similar treatments on the ward during a period of 24-48 hours prior to operation. The limb is wrapped in sterile towels following each treatment. In such cases of repeated application, it is particularly important that the antiseptic used should be nonirritating

neuroses in the direction of their fibers rather than transversely. In the speed with which the wound is opened and closed, fulfilling the aim of the operation is reasonably possible.

The closure of the wound is the most important procedure,

of emergency. In such cases of repeated application, it is particularly important that the antiseptic used should be nonirritating

often a consensus.

meticulous reconstruction is never wasted. Accurate approximation of serosal surfaces, fascial planes, and skin edges, with delicate sutures under minimal tension, rigorous hemostasis, and obliteration of dead spaces are basic to adequate surgery

DRAINAGE OF WOUNDS

In clean operations drainage is seldom required and should be avoided, because the drain itself creates a dead space, acts as a foreign body, and affords access to infection from without. In many cases, drainage of clean wounds indicates indolence or ineptness on the part of the surgeon, who has failed to effect hemostasis. Occasionally, when oozing is difficult to control or when removal of a large tumor leaves a dead space which may fill with serosanguineous fluid, drainage for a period of 24-48 hours is advisable.

1. Localized abscess
2. Residual necrotic tissue
3. Bleeding such as is controllable only by packing
4. Operations involving the gall bladder, bile ducts, or liver parenchyma
5. Unsatisfactory inversion of the duodenal stump
6. Operations on the pancreas
7. Grossly contaminated colon anastomoses

Drainage of the abdomen in the presence of acute diffuse peritonitis is ineffectual, because whatever device is used will be walled off from the major cavity within a few hours. Though the peritoneum may be closed safely in many cases of contamination or infection, it is advisable, by suitable drainage, to anticipate involvement of the less resistant extraperitoneal areolar tissue and subcutaneous fat. Delayed primary closure of the skin is an effective safeguard when nonabsorbable sutures are used to reconstruct a potentially contaminated incision.

Fig. 66—Sites of the more common abdominal incisions

Whether or not to drain a contaminated wound is decided by the amount and character of the contaminant and the natural resistance of the tissues immediately involved. When in doubt, it is safer to drain such wounds until it is apparent that no infection has taken place.

Infected wounds must be left open and drainage maintained by tamponsade or tube. If precautions are taken to protect the subcutaneous fat from contact with deeply seated infected material, it is usually safe to close the angles of the wound up to the drainage tract and thereby shorten the time of healing.

Indications for drainage of abdominal incisions merit special consideration. Normal peritoneum is amazingly resistant to infection. Once inflamed, however, it rapidly loses this happy faculty. The following conditions necessitate drainage of the peritoneal cavity:

INSTRUMENTS

In many teaching hospitals, surgical interns serve for several months as "instrument nurses," becoming thoroughly familiar with the proper names and applications of the tools of their trade. Though this luxury is impractical for the student, and the consensus that details of surgical technique should not complicate undergraduate teaching is probably correct, we feel that the student should be encouraged to learn the names and purposes of instruments in common use. Figs 67-75 display instrument setups routinely associated with various operative procedures at the Royal Victoria Hospital.

SUTURES

Methods of wound reconstruction are governed by many factors. The site of incision, the nature of the lesion, the nutritional state of the patient, the possibility of contamination or infection, and the requirements of drainage—all must be considered in the evolution of a suitably balanced technique.

Continuous sutures should be avoided, except in the mucosal layer of intestinal anastomosis and the closure of peritoneum or synovia. A continuous, removable, subcuticular stitch is useful in some cases. Interrupted sutures are described as plain, mattress, or figure-of-eight. Numerous additional modifications

may be made without tissue strangulation. In debilitated patients the Jones vertical, figure-of-eight interrupted suture, which includes all layers of the abdominal wall except subcutaneous fat and skin, is most effective in closing vertical paramedian incisions. When properly tied, these stitches create a smooth peritoneal surface and do not tear out. The small loop through the anterior sheath of the rectus helps to prevent excessive constriction of the larger bite of peritoneum, muscle, and fascia.

SURGICAL DRESSINGS

Clean wounds, when not drained, require no more than a few layers of plain gauze,

Fig 75.—Skin-grafting instruments: 1, Paget dermatome. 2, Blade for dermatome. 3, Blade holder. 4, Bard Parker blade handle, plastic scissors (Stille), Adson forceps, curved mosquito forceps, and straight mosquito forceps.

need not complicate this text. Mattress sutures more securely grip the tissues they approximate and can be placed so as to effect either eversion or inversion of the apposed edges. Plain, interrupted stitches suffice for flat or convex skin surfaces and most fascial planes. In concavities, such as the groin, vertical mattress sutures are essential to prevent inversion of the skin. The far-and-near interrupted suture, recommended by Whipple for appropriate fascial planes, accomplishes accurate approxi-

mation without tissue strangulation. In the presence of drainage, a small absorbent pad is added.

When pressure is required, to obliterate dead spaces or prevent oozing, stuffed gauze and cotton waste are spread evenly over the innermost dressing and its environment and compressed by elastic adhesive tape.

To prevent it from slipping beneath the surface of the skin, the end of a drainage tube

must be transfixed by a safety pin. If drainage is intended to be of brief duration, a thread, attached to the safety pin and brought out at the margin of the dressing, permits withdrawal of the drain without exposure of the incision.

The dressing of accidental wounds is dealt with in the section on excision and débridement.

technique is usually excellent. Adhesive tape has, to a great extent, replaced the bandage.

Bandages designed to fit conical or cylindrical surfaces or a combination of these, requiring figure-of-eight turns, are referred to as spica bandages. If the surface is cylindrical, spiral convolutions with uniform (2/3) overlapping are sufficient. If the region is conical, a spiral bandage is started at the narrower

Fig 76—Various types of sutures

BANDAGES

The art of bandaging, so meticulously fostered by the French school of a century ago, is lost to many contemporary surgeons. As a rule, the student and intern receive most of their practical instruction in bandaging from nurses in charge of outpatient clinics, whose

extremity and reversed, when necessary, to accommodate the increasing diameter of the part. A spica bandage, secured distally and proximally by two circular turns, consists of a series of overlapping figure-of-eight convolutions and affords the best support to dressings at the junction of one or another extremity with the trunk.

Bandages which envelop dry dressings are best maintained by spiral strips of adhesive tape. When moist dressings are prescribed, commonly in minor infections of fingers or toes, the bandage is first made fast by two or three turns at wrist or ankle, carried obliquely across the dorsum of hand or foot to secure the dressing of the affected digit, and then back again in the opposite oblique to be tied at its proximal origin.

and drained of excess fluid, is ready for use. In hospital and office practice, proprietary plaster bandages and slabs have largely replaced the homemade variety. Their neatness, delicate texture, uniform impregnation, and rapid setting are distinct advantages, which more than compensate for diminished absorptivity.

The requirements of a plaster cast are accurate coaptation, in no greater thickness than

Fig 77—Plaster-of-Paris cast instruments 1, Stille-type plaster-of-Paris shears 2, Cast spreader 3, Stockinet 4, Sheet wadding 5, Plaster scissor (Laster bandage) 6, Plaster knife 7, Stryker cast cutter 8, Plaster bandage 9, Plaster slab

Bandages should afford uniform, firm support to dressings. They must never be so tight as to impede circulation or exert excess pressure on bony prominences or superficial nerves. The resiliency of an elastic bandage is infinitely preferable to the rigidity of plain gauze. In elastic adhesive strapping must never encircle any part of an extremity, nor may circular bandages of any rigid material be applied beneath plaster casts.

PLASTER CASTS

Plaster of Paris is still the medium of choice for immobilizing injured tissues. It is rubbed into strips of coarse muslin which are then rolled into bandages or folded into slabs of various lengths and widths. The bandage or slab, having been dipped in tepid water

the situation demands, and complete immobilization of the part, by inclusion of joints proximal and distal to the lesion, in a position of optimal function. When open wounds are thus immobilized, the absorptivity of the plaster is of great importance. If this quality is impaired, tissue fluid accumulates beneath the cast with consequent maceration of skin, edema of the granulating surface, and an evitable infection. The stain of serosanguineous drainage should appear on the surface of a suitably absorbent cast within a few hours of its application.

Strategic use of plaster slabs greatly diminishes the bulk of a cast without lessening its mechanical efficiency. The slab, of any required thickness, is molded to the under (weight bearing) surface of the extremity and secured by a circular bandage of which 2-4

layers generally suffice. Such a cast is easily removed by a longitudinal cut through its thinner surface and eversion of the cut edges. A thick, cumbersome, irregular cast demonstrates the inexperience of the operator. If the individual who applies a cast is also responsible for its removal, he will soon take steps to improve his technique.

When applied during the acute phase of injury, plaster casts must be carefully padded to accommodate increased swelling and avoid pressure on traumatized soft tissues. For this purpose, a few layers of sheet wadding are effective. Bony prominences, superficial nerves, and weight-bearing areas are additionally protected by pads of felt. At this stage, continual elevation lessens edema and improves circulation. If constant supervision of the case is impossible, as when battle casualties are evacuated from forward areas, it is customary to split the freshly applied cast longitudinally through its thinner surface. This is accomplished most simply when a flattened roll of paper (newsprint is satisfactory), comprising several layers about 2 cm wide, is placed for protection of the skin in the long axis of the limb opposite the slab and incorporated in the circular bandage. While the plaster is still soft, it is easily incised by a sharp blade down to the protective layer of paper. When the split is complete, its edges will spring several millimeters apart, but further separation is prevented and the function of the cast fully maintained by 2-3 circular strips of gauze bandage. If, during transportation of the patient, swelling should obstruct circulation or infection necessitate further treatment of the

wound, the properly split cast may be opened in a matter of seconds by the fingers alone.

When the acute reaction to injury has subsided, muscle atrophy and decreased swelling require that the cast be changed for one that snugly fits the contours of the shrunken limb. The new cast needs relatively little padding. In simple fractures, it is molded over stockinet plus a turn or two of sheet wadding in pressure areas. In compound injuries with persistent drainage, it is applied preferably over sheet wadding which, however, should not be interposed between the absorbent wound dressing and the cast.

The quality of a cast is directly proportional to the operator's experience and personal interest in its composition. Plaster technique, like formal sculpture, is not acquired overnight. Numerous devices in padding, smoothing, and molding greatly lessen the patient's discomfort and expedite restoration of function. Finally, it is axiomatic that when a patient complains of localized pressure beneath a cast he is always right until the affected area has been unroofed for inspection. The pressure lesions caused by ill-fitting casts are often more serious than the initial injury.

Plastic Surgery

Hamilton Baxter, M.D.

GENERAL CONSIDERATIONS

Ancient records of the Egyptians and Indians, written many centuries ago, reveal that they had developed methods of repairing mutilated and deformed features; thus, the origin of this specialty is deeply rooted in the past. Great advances, however, have been achieved in this branch of surgery since the beginning of the 20th century. This revival of interest has been stimulated by World Wars I and II, the invention of new instruments, and recently discovered therapeutic agents.

Plastic surgery deals with the repair of congenital or acquired defects, with a view to restoration of function, improvement of appearance, and resolution of any psychologic disturbances caused by the defect. In recent years, more emphasis has been placed upon the latter aspect, because of the increasing number of handicapped persons injured by warfare and civilian accidents. A facial injury or malformation should be corrected early when possible to prevent the development of deep psychologic wounds. If only partial or no improvement can be accomplished by surgery, psychotherapy should be instituted to aid the individual to become adjusted to the deformity.

Plastic surgery extends into some aspects of general surgery and various surgical specialties. Collaboration is often required between other specialists and the plastic surgeon. In many cases the special experience of the latter in planning incisions, designing flaps,

and obtaining free grafts of various tissues contributes greatly to successful results. This is particularly true, for example, when extensive trauma of skin and subcutaneous tissues has occurred.

A basic sense of artistic imagination is required in which the various stages, in their proper sequence, of a given reconstructive problem can be visualized. The most suitable method of treatment of a specific condition must be selected, due consideration having been given to the physical condition and status of the patient. It is important to diagnose whether tissues have been lost or only misplaced and how they may be restored.

The general principles of wound healing and of the rate of healing of different tissues must be known. The type and rate of healing of a wound is dependent upon the treatment given and the presence or absence of infection. In the absence of infection, healing is firm and strong. During the first four days, termed the lag period, the tensile strength is due only to the slight adhesion of the wound margins by fibrin and to the sutures. Serum, fibrin, leukocytes, and red blood cells fill in the spaces within the wound surfaces, and this initiates the first stage of wound healing. Proliferation of epithelium and connective tissue cells begins early. Subsequently, regeneration of capillaries penetrates the exudate and there is active fibroblastic proliferation. This reparative tissue is termed granulation tissue. After four days, in the absence of infection, the healing of the

wound, indicated by its tensile strength, increases rapidly, reaching a maximum on the 12th-14th day. This is due to proliferation of fibroblasts. Later, the young connective tissue cells shrink, become spindle shaped, and the intercellular collagen fibers contract. Gentle handling of tissues, employing sharp knives, scissors, skin hooks, and atraumatic needles with finest suture materials will aid healing. The blood supply of flaps or tissues being operated upon should be carefully preserved, or the best-planned operation will fail. Positive hemostasis should be obtained by fine ligatures since the use of pressure alone or hot towels may permit hematoma formation which may mar what might have been an excellent result. The type of dressing and amount of pressure applied vary with different procedures and should be considered as the last stage of the operation. The dressing should immobilize the tissues, approximate raw surfaces, minimize edema and oozing of blood or plasma, but should not interfere with adequate blood supply to the area. When elective plastic operations are being performed, no local pustules or general infective process should be present.

TISSUE GRAFTS

Skin Graft.—A free skin graft may be defined as a portion of skin which has been completely severed from its position and has been transferred to another area of the body. The technique of skin grafting has been known for centuries, and it was not an uncommon procedure for gluteal skin to be grafted in order to restore nasal defects. Through the years, surgeons such as Reverdin, Thiersch, Wolfe, Blair and others have described various types of skin grafts and methods of obtaining them. The methods of obtaining split-skin grafts were revolutionized by Padgett in 1939 when he introduced the dermatome. Three main types of skin grafts are used.

Full-Thickness Grafts.—These are dissected from an area of the body which provides skin of suitable color, thickness, and hair distribution to that of the recipient area. This type of graft possesses the advantages of having a good cosmetic appearance, contracting little, and providing a good weight-bearing and

friction-tolerating surface. It is now most frequently used about the face, hands, and weight-bearing areas of the body. The most obvious disadvantages are that these grafts will not "take" on infected areas; cannot be obtained in large quantities, and require extremely careful dressing.

Technique—A pattern of the defect to be covered is made with sterile polyethylene, celluloid, or thin lead sheet. This is then placed on the donor area and the outline traced with a scalpel. One margin of the graft is then raised and, using a small cylindrical object as a roller, the graft is held on tension, which facilitates removal, and is gradually dissected from its bed at the junction of the dermis and subcutaneous fat, none of which should remain on the graft. The donor site is then closed by undermining and suturing the margins of the wound, or, if this is not feasible, by the application of a split skin graft.

Dermatome Skin Graft.—This type of graft may be taken by any of the commonly used types of dermatomes now on the market which permit the cutting of a graft in accurately calibrated thicknesses from thin to almost full-thickness grafts. The *thin* grafts vary from 0.010-0.014 inch in thickness and are particularly suitable for grafting in children where the skin is relatively thin, and in granulating wounds where the take of a thick graft would be doubtful due to the paucity of blood supply or heavy contamination with bacteria. On the other hand, the *thick* dermatome grafts, which usually vary from 0.018-0.030 inch in thickness, provide, in considerable measure, the advantages of the full-thickness graft, without the necessity for covering or closing the large defect which results from the removal of a full-thickness graft.

Technique—When the dermatome has been set to the required thickness of the graft to be cut, the drum of the dermatome and the skin of the donor area are painted with rubber cement which is allowed to dry until the initial gloss of the cement has disappeared. Padgett dermatome cement may be applied and the dermatome drum painted with Plastikrim. The cement adheres to the drum when the skin graft is removed and thus facilitates handling and suturing of the graft. The leading portion

FIG. 78—(See opposite page for legend)

of the drum is then pressed firmly against the donor area, and when the adherence between the two is firm, the drum is rotated upward slightly, and the knife handle is then slid backward and forward until the desired amount of skin is removed. At the end of the drum the skin may be severed with scissors or by pulling the drum away from the skin and cutting through with the dermatome blade. The common reasons for unsuccessful operations of the dermatome are a dull knife,

dressing is changed, any necrotic tissue or exuberant granulations may be scraped away before applying the next dressing. Exudates should be washed away with saline or mild antiseptic solutions. When known pathogens are present, with an increased amount of purulent exudate, they may be controlled by the application of dressings, soaked in a solution of some effective antibiotic for a day or two before the graft is applied. When the skin graft is applied to the raw area, it may be

Fig 78 (cont d) — Langer's conception of the lines of normal skin tension as determined by multiple puncture wounds with a sound pointed metal awl in the skin of cadavers

cement that is too thick or too thin, and moisture on the drum or on the skin. In emaciated patients saline may be injected into concavities, such as between the ribs, to aid in obtaining a complete drum of skin.

Granulating areas may be prepared for skin grafting by covering the region with Xeroform or petrolatum gauze and a firm pressure dressing which is changed at intervals of several days for a short period. When the

laid on healthy granulations, or, if these are not healthy, they may be shaved off with a scalpel or an electrodermatome, carefully, so that the tendons and other important structures are not exposed. The grafts are sutured in place with fine Dermalon and are dressed with Xeroform fine-mesh gauze, several layers of dressings, followed by cotton waste and rubber sponge. The whole dressing is firmly secured with even, firm pressure by band-

and adhesive. Nearby joints should be immobilized by a padded splint.

Failure of skin grafts to live may be due to a variety of causes, both systemic and local. In the first category it may be noted that anemia is most detrimental to successful growth. It has been stated that a hemoglobin below 65% markedly decreases the chance of take of a skin graft. It is good practice not to perform an extensive skin graft if the hemoglobin is below 80%. In patients with severe burns, an effort is made to raise the hemoglobin to at least 85% by transfusions before operating. Other general causes are a

until a later date when the operative procedure may be completed with safety.

Autografts (self) are those taken from and applied to the same person and survive permanently. Grafts between identical twins may be included in this category since they are monozygotic. *Homografts* (same) are those between individuals other than identical twins. They survive for a few weeks and then slough. Homografts are useful as a temporary cover for extensively burned patients while autografts are being applied in patchwork fashion between the homografts to obtain the maximum marginal growth. It may be necessary to obtain

Fig. 79.—Dermatome The electrodermatome may be used to obtain long skin grafts from any part of the body and may also be employed to remove burn eschar or exuberant granulations

high postoperative fever, hypoproteinemia, and hypovitaminosis. The most important local factors interfering with successful healing are an improper preparation of the granulating bed, the presence of virulent pathogenic organisms, insufficient or uneven pressure dressings, and inadequate fixation of joints.

Skin grafts folded with the raw surface approximated and wrapped in moist gauze may be refrigerated at or slightly above 0° C. for several weeks and then be transplanted successfully. If for some reason the patient's condition deteriorates, the operation may be terminated, and the remaining skin grafts preserved

several crops from the same donor area to eke out the supply of autografts. *Heterografts* (other) are portions of living tissue taken from one animal and grafted onto another of a different species. A *zoograft* is a heterograft in which the recipient is a human being; this is no longer used. The term *isograft* should not be used synonymously with *homograft* since *iso-* means equal.

Small Island Grafts.—Large dermatome skin grafts occasionally fail either completely or partially when they are placed on areas which are grossly infected, where the blood supply is inadequate, or in cavities with over-

hanging walls. Successful regrafting may be accomplished by cutting a thin, split dermatome skin graft into small pieces $\frac{1}{4}$ "- $\frac{1}{2}$ " square, and applying these, slightly separated from each other, upon the remaining surfaces of granulation tissue. Wide-mesh Jelonet gauze is secured firmly over the skin grafts, which are dressed every 4 hours with fluffy gauze moistened with physiologic saline, until firm healing has occurred.

Corneal Homografts.—These grafts can be performed successfully, possibly because this tissue is nourished only by lymph. Technical success in many cases was often reduced by clouding of the graft which gradually became opaque because of vascular ingrowth. The local application of aqueous suspension of cortisone to the eye postoperatively appears to be useful in reducing the incidence of cloudy grafts.

Mucous Membrane Grafts.—These grafts may be removed from the lip or cheek and used to restore conjunctival lining of the eye or vermilion border of the lip. Skin grafts when used to replace conjunctiva produce an objectionable discharge.

Dermis.—Dermis consists of the deeper elements of skin, the epithelium having been removed either with a dermatome or a razor. It may be inserted beneath the skin to fill depressions, it shrinks less than fat. Sheets of dermis have been used to reinforce large hernial defects. Thick dermatome skin grafts may be resplit on the dermatome by setting the blade at half the previous thickness and removing the deeper layer of the graft in a single sheet, thus doubling the surface area of the graft. The dermis takes well and regenerates a new epithelium rapidly. The surface is paler than that of an ordinary skin graft because few pigment cells are present.

Fat.—Fat may be used to fill depressions, particularly those about the face. Rigid asepsis and atraumatic technique are essential in obtaining the graft. Shrinkage after grafting amounts to about 40%, so that a defect should be overcorrected. It is less extensive if large pieces are grafted. About half the cells die, but those which survive form the fat graft that remains. Abdominal fat grafts will increase in size, if the patient deposits additional abdominal fat. Fat may be combined with

dermis or fascia, which provides a firmer tissue with less tendency to shrink, due either to degeneration or absorption.

Fascia.—Fascia is most frequently used to form slings which are employed to support the drooping cheek and mouth following facial paralysis or to raise the eyelid in ptosis. Fascia is also used in arthroplasty, to replace tendons, or to prevent adhesions between tendons and adjacent structures. It is abundantly available from the fascia lata of the thigh, from which it may be removed, by direct exposure or through a small incision with a fascial stripper. Autogenous grafts are preferable since it has been shown that the cells remain viable after transfer in human beings.

Muscle.—Muscle is rarely used as free grafts, but flaps of masseter or temporal muscle with blood and nerve supply preserved are employed to provide correction of facial paralysis.

Artery and Vein Grafts.—These grafts are discussed in Chapter 33, *Peripheral Vascular Diseases*.

Cartilage.—Cartilage has many uses as a free graft, chiefly to fill in bony depressions about the face. It has many advantages since it does not shrink, may be carved easily, and provides a resilient support for soft tissue. Cartilage is probably most frequently used in the reconstruction of the saddle nose. It should be noted that in children, cartilage grafts must be repeated, since the graft does not participate in the general growth of the area. Most surgeons prefer to use fresh autotransplants, the cells of which survive and do not absorb. However, either fresh or preserved homografts may be used, although marked absorption usually occurs in time. Cadaver cartilage may be sterilized by placing it in a glass jar containing physiologic saline solution and exposing it to 4,000,000 r from a powerful cobalt⁶⁰ source. The cartilage is then stored at room temperature until required.

Tendon Grafts.—These grafts are almost exclusively employed to replace missing or damaged tendons. The palmaris longus tendon or the long extensor tendons of the toes, removed with paratenon, are those usually chosen for tendon grafting in the hand. Tendon grafts have been advocated instead of fascial slings, in facial paralysis, in the belief that fewer ad-

hesions which limit motion would form about a tendon with its paratenon. They may also be inserted as a pad in retruded upper lips or other parts of the face following congenital or traumatic deformities, to restore normal contour.

bone grafts appear to survive. However, in dense cortical bone grafts where the cells die because of lack of nutrition, the transplant is replaced by ingrowth of cells from the host bone and periosteum. Autografts are preferable in plastic surgery, since healing is more rapid,

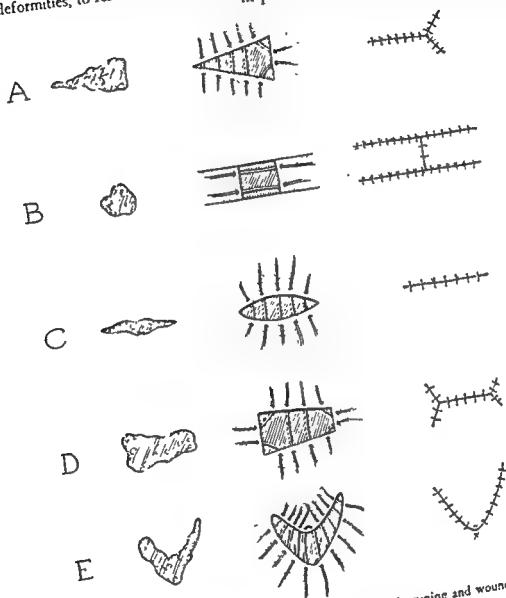

Fig. 80.—Various methods for excising defects with free undermining and wound closure

Bone Grafts.—Bone grafts are indicated when a rigid supporting tissue is necessary and are used to repair mandibular, cranial, and sometimes malar and nasal defects. Pedicle grafts of bone and osteoperiosteal grafts are rarely used. Functional use in contact with living bone is essential for retention of the calcified matrix of autogenous rib, tibial, and iliac bone grafts. Most of the cells in cancellous

although bone bank material may be used in circumstances contraindicating the use of autogenous bone. The usual source is the crest of the ilium, but the ribs, tibia, or fibula may be used. Cancellous bone chips from the ilium have been employed successfully in forming molded bone grafts for reconstruction of contour bone defects of the face. Two advantages of these grafts are that they can survive and

consolidate even in the presence of mild infection and tedious carving is not required.

Nerve Grafts.—These grafts are occasionally required following loss of substance of the facial nerve or nerves in the hand. Autografts are required and have been described by Bunnell, Ballance, and Duel.

Composite Graft.—First described by Koenig, these grafts are obtained from the helix of the ear and consist of two skin-covered surfaces and intervening cartilage. These may be used to repair defects of the ala, tip, and columella of the nose, with excellent results.

if rigid support is required, a strip of cartilage must be added later.

Skin Defects and Pedicle Flaps.—Removal of a scar, area of granulation tissue, or a tumor may be accomplished by elliptical excision and immediate closure of the defect by suture. If the wound is not large, this may be accomplished by undermining the adjacent skin and approximating the skin edges by suture. The resulting straight scar is most inconspicuous, particularly if it is parallel to Langer's lines of skin tension. Larger defects may be eliminated by converting the defect into a

Fig. 81.—Method of formation of tubed pedicle flap.

A, Outline of staggered skin incisions to facilitate closure of the wound at each end of the tube. A number of points are marked opposite each other on the flaps to indicate the correct site for insertion of sutures to form the tube.

B, Following free undermining, the wound left by formation of the pedicle is closed by sliding flaps of skin beneath the tube and suturing securely. If the defect is too wide, it should be covered with a split skin graft.

Full-thickness loss of the eyelid has also been replaced with this type of two surface graft with a cartilaginous support to maintain its shape. The exact curvature desired may be obtained by selecting an appropriate site on the helix. The defect in the helix may be repaired by attaching a skin flap from the postauricular region which is severed at its base about two weeks later, folded, and sutured to the posterior edge of the defect. A full-thickness section of the lobule of the ear may be grafted in the same way to restore nasal defects, but

square, triangular, or other geometric shape; then by undermining and freely shifting local skin flaps, the deficiency may be overcome. Those procedures, which are least complicated as to rotation of tissue and in which the length of the scar is minimal, are usually the most satisfactory.

A skin flap may be defined as a given amount of skin and subcutaneous tissue which is attached to the body at some part of its periphery, through which it receives its blood supply. This flap may be rotated from its

Fig 82.—A, Avulsion of soft tissues of heel when foot was run over by train.

B, Cross leg pedicle flap after being delayed was swung over into defect on foot.

C

D.

original site to fill an adjacent defect and is called a *simple* or *open flap*. The blood supply to a flap may be increased by raising part and then suturing it back in its bed. This is called a *delayed flap*.

A *tubed flap* eliminates raw areas and chronic infection present in open flaps. The desired width and length of the flap having been determined, parallel incisions are made through skin and fat, and the strip of skin is undermined. Points opposite each other on the flap, previously marked with dye, are sutured with the skin surface outward. The lateral skin edges are undermined and closed with sutures. If the

applying a skin graft to the raw undersurface of a flap. These are useful in repairing loss of two surface structures such as the cheek, lip, nose, or eyelid.

An *island flap* consists of an area of skin and subcutaneous tissue attached and nourished only by blood vessels and a small amount of subcutaneous tissue. This flap is often used to transplant an island of scalp to reconstruct an eyebrow.

Z-Plasty.—Contraction of scar tissue may cause limitation of motion of joints; in many cases a heavy ropelike cord of scar tissue forms in the line of tension of scar over the area

Fig. 83.—Use of Z-plasty to relieve cicatricial contracture

A, The Z incision with angles of about 60 degrees to obtain optimum increase in length

B, The flaps transposed after free undermining

C, Skin closure with correction of the linear contracture

tubed flap is too wide to permit closure of the raw wound by undermining, the raw area is covered with a skin graft. These flaps which form solid tubes of skin and fat attached at each end to the body may be transferred rapidly from one part to any other part or extremity, by attaching one end to the wrist or arm as a carrier. When the blood supply from the arm is adequate, the opposite end of the tube is severed and the whole flap is swung to the recipient site and sutured in place.

A *lined flap* is formed by folding together the raw surfaces of one end of the flap or by

affected. The heavy scar may be partially excised and by suitably placed Z-shaped incisions with transposition of the two flaps, the bow-string tension may be overcome. The area adjacent to the flaps should be extensively undermined. This procedure causes an increase in length of the contracted scar. Mathematically it has been shown that the most practical angle for outlining the two flaps in Z-plasty is 60 degrees. The percentage increase in length of the contracture is 75%. In the case of long bundle scars, double or triple "Z" incisions may be made in series with still greater relaxation

resulting than that obtained by a single incision. When broad scar bands have formed, for example, in chest and arm adhesions following severe burns, the shifting of local tissue flaps may be combined with free skin grafts.

Hypertrophic scar.—A hypertrophic scar is one in which there is excessive formation of fibrous tissue and is often seen following deep second and third degree burns or infected wounds. Many of these scars subside spontaneously in time, or their departure may be hastened by a course of x-radiation.

ischial, unilateral or bilateral. The incidence of pressure sores in civilian patients treated in paraplegic therapy centers is much lower.

Etiology

The development of decubitus ulcers in spinal paraplegics is due to intrinsic and extrinsic factors.

Intrinsic Factors.—The most important intrinsic defect is the lowering of tissue resistance to pressure which is pronounced during the

Fig 84.—Multiple decubiti involving the sacral, ischial, and trochanteric regions. Necrosis of deeper tissues has resulted in extensive undermining of skin edges, with formation of sinuses and bursae.

Keloid.—A keloid may be easily recognized since the growth of fibrous tissue extends beyond the original limits of the wound and sometimes occurs following minimal trauma. Excision and skin grafting followed by early irradiation appear to be the most effective treatment.

DECUBITUS ULCERS

As a result of World War II, the numbers of paraplegic patients were greatly increased. Many of these developed large bed sores, which seriously complicated their condition. The majority of these individuals developed multiple ulcers, and the combinations most frequently seen were sacral, trochanteric, and

stage of spinal shock. This is caused by interruption of spinal vasomotor control and flaccid paraplegia, not only of the skeletal muscles but also of the muscular wall of internal organs and vessels. Thus, paralytic vasodilatation is produced in these areas. The second most important intrinsic factor is sensory loss in the paralyzed regions which prevents the paraplegic from feeling the sensations of numbness or pain normally arising from an area exposed to undue pressure and consequent reduction in blood circulation. The stimulus to request a change of posture is lacking. The third factor is the thickness of fat and muscles between the bony prominences and skin of certain weight-bearing areas of the body. Other

intrinsic factors are spasticity of the paralyzed limbs, nutritional deficiency, anemia, and infection

Extrinsic Factors.—Exposure of the skin to moisture from excreta tends to cause maceration and should be avoided. The other factor of cardinal importance is pressure, which leads to ischemia and represents the immediate cause of development of ulcers. Decubitus ulcers occur over bony prominences, where the padding is thinnest and the pressure is greatest. The effect of shearing stress is more injurious than vertical pressure, since the former decreases the blood supply of larger areas

Pathology

The degree of ischemia, virulence, and direction of extension of infection along fascial planes distinguishes various stages in the development of decubitus ulcers. Transient circulatory damage has occurred when pressure has caused erythema of the skin with some edema but without death of the tissues. Relief of pressure and gentle massage will cause these symptoms to disappear. When permanent damage has developed, the epithelium may be separated from the dermis by exudation of plasma, and if the pressure continues, necrosis of the deeper layers of the skin will follow with formation of a black area of full-thickness skin destruction. Deep penetrating necrosis may involve fascia, muscle, and bone with undermining of skin edges, ramifying sinuses, infection of joint spaces, and osteomyelitis. The sores always become infected with mixed organisms, including staphylococci, *E. coli*, protei, and *Pseudomonas aeruginosa*. Sepsis and death most commonly result from infection of the urinary tract or from the decubitus ulcers

Treatment

General

The local treatment of pressure or bed sores in paraplegics must be correlated throughout all stages of treatment with maintenance of the optimum general physical condition. A high caloric, protein, and vitamin diet will prevent nutritional deficiency and help to maintain a positive nitrogen balance. Anemia may be treated by blood transfusions at regular inter-

vals. Daily administration of 25-50 mg of testosterone has been reported to accelerate healing of the sores

Local

During the period of spinal shock which occurs immediately after paraplegia has developed following trauma, the patient is most susceptible to the formation of sores. Prevention rather than treatment is the objective, and the cardinal method of prophylaxis is change of posture at least every 2 hours *day and night* to redistribute pressure. Later on, every 4-6 hours is sufficient. Oscillating beds and foam rubber or intermittent pressure mattresses are useful mechanical aids. Hygiene of the skin is important, and it should be kept dry and free from contamination by feces or urine. Once sores have developed, the principle of frequent change of position is enforced even more vigilantly. When necrotic tissue has demarcated, the slough should be excised to permit drainage of infected material and reduce toxic absorption. The wound is dressed daily with gauze moistened in an appropriate antibiotic solution or mild antiseptic and secured by Elastoplast. When granulations have formed, skin grafting will complete healing of the ulcer. Intractable spasticity of the legs not only delays healing and creates new sores, but may render plastic repair of an ulcer difficult if not impossible. This troublesome condition may be eliminated by intrathecal alcohol injections.

Plastic Repair.—In instances where very extensive or recurrent sores persist, rotation flaps or other reconstructive procedures may be required. Prior to operation it is essential that the general condition of the patient should be improved as much as possible and that renal infection and diarrhea must be overcome

Sacral Ulcers

1 *Direct closure:* Excise all scar tissues and any bony prominences. Undermine and close without tension.

2 *Single lateral rotation flap:* A flap is rotated into the defect after removal of all sinuses and prominent bone. The secondary defect, caused by shifting the flap, is skin grafted.

3 *Double flaps:* This is a useful method, especially if the flaps from the buttocks are based inferiorly

4. Skin grafts are used only as a temporary cover, since they tend to break down.

Ischial Ulcers.—

Excision and direct closure: All scar tracts must be excised together with the gluteal bursa. The ischial tuberosity is removed if involved. Resection of the ischium is reserved for thin patients with a recurrent ulcer.

Trochanteric Ulcers.—

Following wide removal of the ulcer, bursa, and bony prominence, a rotation flap of skin based anteriorly on the thigh is swung over the defect. The secondary defect is skin grafted.

Postoperative Care

Most sores are on the posterior aspect of the trunk, and the patient may be conveniently

Fig. 111—A, Sacral decubitus ulcer showing tissue excised, undermining, and closure by two rotation flaps.

B, Sacral decubitus ulcer showing a preliminary delaying procedure of a single pedicle flap, which was later rotated into the defect created by excision of the undermined ulcer and bony prominences. A thick split skin graft was used to close the defect created by rotation of the flap.

C, Ischial decubitus ulcer deeply undermined and involving the tuberosity. Repair by complete excision of the undermined ulcer and tuberosity and suture of muscles and skin in several layers with stainless steel wire.

D, Trochanteric decubitus ulcer with exposure of the greater trochanter. The trochanter is excised and the adjacent muscles swung into the defect. A skin graft is used to close the defect.

nursed in the prone position. The bowels are prepared with enemas preoperatively and then not opened, if possible, for a week. Blood transfusions are usually necessary to counteract surgical shock. If a hematoma forms beneath a flap in spite of insertion of a drain, it should be evacuated immediately. Flexion of the hips is not allowed for 3 weeks after healing of ischial and trochanteric sores. Finally, the patients should receive training in a rehabilitation center, where they will be instructed about the danger of pressure and how to avoid it.

CONGENITAL AND ACQUIRED DEFECTS

Some children have the misfortune to be born with congenital defects of various types. Cleft lip and palate will be discussed in a later section.

A rather common congenital defect in children is *lop ears*, quickly noted by playmates who ridicule the victim until an inferiority complex develops. Fortunately, this condition can be corrected by a simple operation which

Fig. 86 - A and B Protruding ears which are large, show no antihelix, and stand out at right angles to the head

C and D Postoperative result achieved by the operative procedure described. Note the reconstruction of the missing antihelix.

FIG. 87 —*A*, Marked saddle nose following childhood infection of septum.
B, Reconstruction with cartilage graft

FIG. 88 —*A*, Long hump nose with a drooping tip
B, Six months after operation. The hump was removed, septum was shortened, and the alar cartilages were reduced in size

may be performed under local anesthesia. An ellipse of skin is excised with its long axis at the cephaloauricular junction, and a small ellipse of cartilage is also removed where the new antihelix is to be formed. The cut edges of the cartilage are infolded with sutures, and following closure of the skin incision a pressure dressing is applied. Excellent cosmetic results may be obtained as well as relief from the inferiority complex.

Congenital or acquired deformities of the nose may interfere with function, as well as create an unesthetic appearance. Obstruction to respiration should be corrected before or, if feasible, at the time of plastic reconstruction of the nose. Local anesthesia is the anesthetic of choice for rhinoplasty. Following the usual skin preparation and draping, incisions are made between the alar and upper lateral cartilage on each side and extended medially to

Fig 89

Fig 89—Rhinophyma increasing in size steadily, causing patient to stay at home during the day to avoid embarrassment

Fig 90

Fig 90—Postoperative result after raising skin flaps, excising hypertrophied sebaceous glands and resuturing flaps after trimming away excess skin

Carved autogenous cartilage transplants and cancellous bone from the ilium are most satisfactory materials for reconstruction of a *saddle nose*. The graft is carved to the proper size and is inserted through an incision in the tip of the nose. Grafts of bone should be brought in contact with bone by sliding the upper end under the periosteum, otherwise they tend to be absorbed. If tip support is required, a separate strut of bone or cartilage is inserted in the columella and attached to the piece of graft restoring the bridge. After closing the incision, a nasal splint is then applied to control swelling. One disadvantage of the use of bone grafts in the nose is the subsequent lack of normal resiliency of the nasal tip and the possibility of fracture of the graft

separate the columella from the tip of the septum. The skin is now separated over the rest of the nose. The hump is removed with a saw at a predetermined level, depending on the individual case, and the upper lateral cartilages are trimmed to the same level. The nasal bones are separated with a saw from the septum. At this stage the septum should be shortened and the alar cartilages reduced in size if necessary. The nasal bones are now cut on each side, at their junction with the maxillary bones, and fractured. The columella is sutured to the tip of the septum with dermal sutures, and a nasal splint is applied. This is changed when necessary and discarded in a week or two.

Rhinophyma begins with acne rosacea and terminates with tremendous hypertrophy of the

sebaceous glands, often completely obliterating the normal contour of the nose. Several methods of treatment have been suggested.

1. Flaps of skin on the nose may be raised, the hypertrophied glands excised completely, and the flaps resutured after trimming away any excess skin.

2. Complete excision of affected tissue and application of a free skin graft.

3. Finally the growth may be pared down to the normal contour of the nose without removing all regenerative elements.

hypertrophic, sometimes request a plastic operation. The breasts should be free from evidence of malignancy, no serious systemic disease should be present, and there should be no history or evidence of psychosis. Many operations have been devised, and some are suited to particular types of cases. Massive hypertrophy of the breast is easily treated by reflecting skin flaps after making an inverted "T" incision, amputating all excess breast tissue, and fashioning the remaining substance into a cone shape by interrupted sutures. The skin flaps are ap-

A

B

C

D

Fig 91—A and B, Marked fatty hypertrophy of breast, causing backache because of weight and difficulty in obtaining attractively fitting clothes

C and D, Result one year after operation, with relief of symptoms. Note cone shaped breast contour

Re-epithelization from remaining sebaceous glands occurs in about 10 days. Each method possesses certain advantages, and all factors should be considered in selection of treatment for each case.

Mammoplasty.—Individuals with pendulous breasts, either flabby and atrophic or markedly

proximated to form a tight skin brassière which supports the breast. Excess skin is excised and the wounds are closed with fine sutures. The nipples which have been excised are replaced at esthetically suitable levels, which were marked before operation. A circular patch of epithelium is excised with a sharp scalpel, and

each nipple is sutured carefully to the dermis. A firm supportive dressing is applied. A second type of operation commonly used in smaller breasts is removal of the required amount of the lateral part of the breast by an S-shaped incision. The lower free end is rotated upward and medially and sutured to the upper end of the incision in the gland, thus re-establishing the cone shape of the breast. Each nipple is transposed to a predetermined new level and brought through a circular hole in the skin which is the same size as the nipple. After replacing the nipple, draping, and suturing a tight brassière formed from the skin flaps, a pressure dressing is applied. In each case it is

Baggy skin in the eyelids may be removed by incisions placed in wrinkle lines in the upper lid and 1 mm below the eyelashes in the lower lid. The incision for the face and neck starts in the hairline above the ear, curves in behind the tragus, emerges and crosses the lobule, and extends up behind the ear to the hairline. The skin should be undermined close to the eye, nostril, and mouth and down into the neck. The skin envelope is drawn up tightly and all excess is excised. Subdermal sutures, as well as skin sutures, are used to close the wound. A pressure dressing is applied for a week, and the face should be supported at night for a month.

Fig 92—A, Stump of proximal phalanx of thumb following severe electric burn

B, Reconstruction with bone graft and tubed pedicle flap 10 years later.

C, Patient has powerful grasp and wide range of movement. Regeneration of sensory nerves (pain, heat, and cold) has extended to tip of thumb, which enables the patient to avoid thermal and other forms of trauma.

advisable to insert a small drain in the wound, removing the drain in 48 hours.

Meloplasty.—With the loss of weight or with increasing age, the elasticity of the skin is decreased and the skin falls into wrinkles. This sign of aging is a matter of considerable importance for many, for business as well as social considerations.

These wrinkles may be removed from the forehead by incising in the hairline and undermining the skin down to the eyebrows. The excess skin is removed and the wound sutured.

Reconstruction of Extremities.—Loss of the thumb reduces the efficiency of the hand by one half. The thumb may be reconstructed by phalangization, pollicization of the index finger, and use of local skin flaps or tubed pedicles, with insertion of a bone peg for support. When skin and subcutaneous tissues have been avulsed from the hand, exposing tendon and bone, it is necessary to cover the defect by shifting local flaps or applying a pedicle flap from another area. One of the most suitable sites is a flap from the lower abdomen,

lata for the suspension of the paralyzed face. It is thought that less tendency to form adhesions which limit motion occurs when this type of graft is used.

Skin Excision.—Following a facial paralysis of some years' duration, the skin sags in redundant folds. In conjunction with fascial or muscle suspension operations a modified meloplasty may be performed and all excess skin excised.

Fig 91.—Method of using fascial strips to support paralyzed facial muscles

CLEFT LIP AND PALATE

Introduction

Egyptian mummies have been found showing this congenital deformity, and Celsus is credited with being the first to repair cleft lips by paring the margins and suturing the wound. According to the latest surveys it has been found that cleft lip or palate occurs once in 750-850 living births in a Caucasian population, although the incidence is only half as frequent among Negroes. A cleft lip is approximately twice as often situated on the left side and is more frequent in males.

Embryology

The classical concept of development of the component structures of the lip, alveolar process, and palate by growth and subsequent coalescence of five various processes about the primitive oral cavity has been questioned by a number of investigators during the past 30 years. According to Veau there are no processes and clefts. The nasal orifices are formed by invagination of the surface ectoderm. The ectoderm is invaded by the mesenchyme growing into the lip and subnasal region, from the lateral part of the face. Thus, the primitive primary palate and lip are formed. Only in the posterior palate is there fusion of processes from either side. Failure of mesenchymal pene-

Fig 93.—A, Correction of facial paralysis with two muscle pedicles obtained from the anterior part of the masseter muscle. Care must be taken to avoid injury to the parotid duct and to the nerve supply of the muscle strips.

B, Facial paralysis may also be corrected by muscle pedicles carried down to the corner of the mouth and into the upper and lower eyelids.

tration at the 11 mm. stage may thus result in various types of cleft lip or palate, due to rupture of the thin epithelial partition by the strain of constantly growing facial structures

Recently, Stark has studied serial coronal sections from the lip to the oropharynx through the heads of five human embryos with clefts of the lip or palate. The volume of mesoderm present on all sides of the clefts was calculated after making planimetric measurements. When mesoderm was present on one side and not the other, a cleft lip occurred on the side that lacked mesoderm. When mesoderm was absent on both sides, a bilateral complete cleft lip occurred. The hard and soft palates are formed by fusion of two lateral processes which grow toward each other and fuse in the midline. Since mesoderm was present in the palatal areas of all the embryos with a cleft palate, he postulated a relative lack of mesoderm rather than a complete absence to explain the presence of a cleft palate.

Fraser et al. have reported the results of experiments on the process of closure of the palate of the mouse *in vivo*. When the palate is about to close, the palatine shelves project vertically downward on either side of the tongue. A force presumably develops within the shelves, which causes a transition from the vertical to the horizontal plane. There is a bulging inward of the medial side of the shelf, with a concurrent retraction of the ventral border. This process begins posteriorly and proceeds anteriorly in a wavelike motion, until the two shelves rise above the tongue to meet in the midline, if the width of the head and the shelves is appropriate. The mechanism of palatal closure involves the delicate integration of a number of processes, each under the influence of genetic and environmental factors.

Recent work of the school of experimental embryologists shows that specific organs and tissues are induced by "organizers" and also by the action of various chemical substances upon embryonic cells. These organizers act on embryonic cells and alter their pattern of growth. The development of the optic cup from the neural plate, for example, is induced by a portion of the archenteric roof immediately beneath it. It has been shown that any

lack of direct contact of the cells with the organizer will prevent or modify the development of specific tissues or organs.

Etiology

The precise cause of this condition has not yet been established with certainty. While the commonly suspected conditions of alcoholism, syphilis, falls during pregnancy, and malposition of the fetal hands or tongue have been blamed, there is no doubt that these can be excluded in favor of other possibilities, such as vitamin or other dietary deficiencies as well as rubella and acute infections occurring during the first trimester of pregnancy, which may exert an adverse effect on the product of conception. It has been claimed that pregnancies occurring late in the reproductive life of the mother tend to produce a greater number of children born with congenital defects. A recent study does not confirm this conclusion. It must not be forgotten, moreover, that there is a definite positive family history in 20-30% of cases. Warkany believes that cleft lip and palate are inherited as a double recessive trait, one gene being autosomal and the other sex-linked. According to Fogh-Andersen, cleft lip with or without cleft palate should be considered hereditary, whereas other factors are responsible in isolated cleft palate. It has been found that offspring of pregnant mice treated with cortisone show a high incidence of cleft palate as well as other defects. X-irradiation of pregnant laboratory animals results in a high incidence of congenital anomalies in the offspring. Different types of deformities may be created by administering the x-rays at various periods of gestation, when certain organs or structures are in a critical stage of development.

Types

The cleft of the lip may be unilateral or bilateral, partial or complete. A cleft palate may involve merely the uvula or extend into the soft palate, hard palate, and finally through the alveolar ridge, when it is associated with a complete cleft lip and palate. In the simplest variety the cleft of the lip may result in notching of the vermilion border, and there is usually a muscular defect and asymmetry of the nostril on the affected side. When the

A.

B.

C.

Fig 96—A, Thompson operation (modified) A and A' are marked with methylene blue at the base of the columella and the nostril but retaining sufficient tissue on each side to form a floor for the nostril equivalent in width to the opposite nostril. The vertical length of the lip on the normal side is measured with a compass from the base of the nostril to the vermillion border of the lip. Fixing the regulating screw at this length, measurements are taken in the lip at each side of the cleft, commencing at A and A' and extending to B and B'. The latter points are placed at the junction of the skin and vermillion of the lip. The margins of the cleft are now denuded with a single stroke of a narrow bladed scalpel. The nostril and skin of the cheek on the cleft side are undermined freely as in the internal lining of the skin of the ala and tip of the nose. Correct relationship of the external and internal skin surfaces of the ala is maintained by through and through mattress sutures tied over a small piece of Xeroform gauze. The muscle layer of the lip is approximated with several No. 5-0 catgut sutures. The skin edges are sutured with interrupted No. 4 stainless steel sutures, and after excising the excess vermillion in the form of double V-shaped flaps, these are imbricated and sutured with No. 5-0 Dermulon sutures. A Logan lip bow is then applied to immobilize the lip.

B, Appearance of preoperative partial cleft lip without palatal defect.

C, This procedure simulates the normal philtrum and in suitable cases provides a full, well shaped lip.

condition is more marked, the notching of the lip extends for a varying distance toward the nostril and there is frequently notching of the alveolar process. In yet another type the cleft involves the floor of the nostrils; the nostril is markedly widened and the alveolar process is cleft.

Operation

Cleft Lip.—The opportune time for operation is from 6 to 8 weeks after birth. There are

those who advocate operation within the first week of life, but since there is never an emergency due to feeding problems, there is no reason for not taking advantage of the better condition of the patient and larger and more easily handled tissues of the lip when the child is somewhat older. Consistently better results can be obtained when the child is in good condition and has reached a weight of 9-10 pounds. The ideal operation should result in

Fig. 97.—A. Hagedorn-LeMesurier operation. The points *A* and *A'* are located as in the previous method. The point *D'* is selected on the mucocutaneous border of the cleft side as high up as possible where the mucous membrane is adequate in thickness. From this point a line *D'C'* is extended perpendicularly from the vermillion border and varies from 3.5-4.5 mm. in length, depending on the age of the child. The lines *A'C'*, *C'B'* are of equal length. The latter curves slightly toward the vermillion border. This produces a moderate pouting of the lip which is a normal characteristic. On the medial side a line *AB* the same length as *A'B'* is drawn down to the vermillion border, and a line *CD* is extended into the lip at right angles to the mucocutaneous border. This is the same length as *CD'*. Incisions are then carried out as shown in *A*, and after free undermining of the cheek and lining of the ala, the flaps are approximated as illustrated in *A*. The muscle layer and skin edges are sutured with fine catgut and wire as previously described.

B and *C*. Preoperative and postoperative photographs showing the full pouting lip which is obtained.

a nostril of the size, shape, and position similar to that on the opposite side—a full, loose lip and a symmetrical vermillion border, simulating a cupid's bow if possible, and a faint scar. Prior to operation the child should be free of obvious respiratory infection, and the skin about the lip should be clean. The most satisfactory anesthetic is endotracheal gas and

oxygen supplemented, when necessary, by ether. This provides the operator with sufficient time for a leisurely and planned operation. If the hemoglobin is lower than average, a blood transfusion should be given of 100-150 ml., and this may be administered through the femoral vein or into the long saphenous vein at the level of the internal malleolus. Since

Fig. 98.—A, Operation for bilateral cleft lip. The incisions ABC are outlined on both sides of the cleft and on the probulum. After very extensive freeing of the nostril and cheek from the maxilla on both sides, suture of the muscle layers and skin margins is carried out as described in single cleft. The vermillion border is imbricated and a Logan lip bow is applied. A full, well-balanced lip is obtained by repairing both sides at the same time.
B and C, Preoperative and postoperative photographs.

the type of deformity varies considerably, it is helpful to employ the Thompson, Mirault-Blair, or Hagedorn-LeMesurier procedures when indicated, depending upon the type of cleft

Bilateral Cleft Lip—This type of deformity requires quite a different procedure from those employed in the single cleft lips, in order to

avoid unsightly tight lips, too frequently seen. The premaxilla, if protruding, should never be replaced posteriorly by excising a wedge of septum or even by splitting it obliquely and sliding the premaxilla back. In the past, this practice has been one of the most common causes of severely retracted upper lips. The object to be achieved is the displacement of

Fig. 99—Posterior and lateral views of the palatal muscles are illustrated

Fig 100.—A, Dieffenbach-von Langenbeck operation Through lateral incisions, mucoperiosteal flaps are raised from the hard palate with a curved elevator The major palatine artery is spared The palatal spongy tissue is severed and the medial margins of the soft palate are split or pared so that an even raw surface is prepared for suturing The hamulus may be fractured but only if necessary to secure adequate mobilization of the soft palate The nasal mucosa is sutured in a separate layer with fine catgut sutures so the knots project into the nasal cavity. The muscle layer and oral mucosa are then sutured with horizontal mattress sutures of Dermal, including both surfaces of the uvula A single large stay suture may be inserted in the soft palate if desired

B, Cleft of palate with minimal scarring following von Langenbeck operation No speech therapy was required

C, Healing of palate with minimal scarring following von Langenbeck operation No speech

the premaxilla posteriorly by traction of the repaired lip muscles, causing it to assume a relatively normal relationship to the maxilla. Marked interference with its blood supply will inhibit normal growth. In this type the cleft may be complete or incomplete, as in the single lip. Following operation for cleft lip, the suture line is kept clean by swabbing with cotton-tipped applicators dipped in penicillin solution 1:1,000, until bleeding and crust formation cease.

The baby may be fed by a small glass syringe or may be allowed to drink from a small cup or glass. The sutures are removed as indicated, starting on the fourth day. Application of arm splints for the entire postoperative period will prevent the child from injuring the healing lip.

Cleft Palate—The goal of cleft palate surgery has long since advanced from the concept of merely providing an intact partition between the oral and nasal cavities. With improvement in technique it has become obvious that the function of normal speech is the aim to be achieved in every case. This must include the services of the speech therapist, orthodontist, and, if necessary, the prosthodontist. The ability of the soft palate to move freely upward and backward and close the nasopharyngeal sphincter is the test of a successful operation, and those procedures which may interfere with this function of the soft palate should not be employed. In 1764, Le Monnier, a French dentist, reported the first successful repair of a cleft velum.

The optimum time for closure of the cleft palate is between 18-24 months. The reason for this is that there is a marked increase in length of the soft palate from birth until about 1½-2 years of age, followed by little growth until about 5 years, when a gradual increase in length occurs. A cleft palate does not materially affect the nutrition of the child, although a higher incidence of middle-ear or sinus infections occurs in these individuals. This probably results from the admission of oral contents into contact with the nasal passages. The types of operations most commonly carried out are as follows:

The von Langenbeck Procedure—Longitudinal relaxation incisions are made near the teeth. The mucoperiosteal flaps are raised from

the hard palate and elevated toward the midline after severing the palatal aponeurosis and fracturing the hamulus. These may be felt as small bony prominences in the anterior and lateral part of the soft palate on each side. The margins of the cleft are split or carefully pared, removing only the mucous membrane. The nasal side of the mucous membrane is then approximated with a number of interrupted catgut or dermal sutures, with the knots projecting into the nasal cavity. A large horizontal mattress suture is carried from the lateral border of the soft palate, on one side, to the opposite region, where it serves as a restraining hammock to splint the muscles of the soft palate during postoperative healing. The margins of the cleft in the oral cavity are then approximated with horizontal mattress, dermal sutures from the anterior termination of the cleft and extending into the soft palate and over the posterior aspect of the uvula.

The patient is fed a liquid diet, which is gradually changed to a soft diet at the end of a week. The sutures are removed in approximately two weeks, and subsequently normal diet may be resumed.

Other Procedures—In clefts involving only the soft or part of the hard palate, a U-shaped incision may be made medial to the teeth from one maxillary tuberosity to the other, and the whole mucoperiosteal flap which has been raised may be set back after stretching the major palatine arteries from the posterior palatine foramen. The cleft which is present is closed at the same time in the manner previously described.

Occasionally, a "set back" may be performed secondarily on an intact repaired palate which is too short to permit good speech function. The raw surface thus exposed on the nasal surface of the palatal flap may be skin grafted in an effort to minimize scar contracture of the raw surface.

Another method of obviating the raw area on the nasal side of the palatal flap is to dissect free the mucosa covering the nasal surface of the palatal bone but to leave it attached posteriorly to the soft palate. When the entire palate is subsequently displaced posteriorly, the strip of mucosa on either side may be sutured to cover any raw area on the nasal surface of the mucoperiosteal flap.

In complete clefts of the palate, another procedure which is of great value is the vomer flap, by means of which the cleft in the hard palate is closed by inserting a flap of mucosa from the vomer underneath the edge of a mucoperiosteal flap which has been raised on the opposite side of the palate.

Persistent small perforations which occasionally occur following a palatal operation, due to separation of the suture line, may be closed by freshening the margins of the perforation and resuturing the marginal defect, after relaxation incisions have been made.

When primary surgical repair followed by a reasonable period of speech therapy has failed to result in normal speech, other surgical procedures should be considered. One method is to elevate a pharyngeal flap containing mucosa and muscle, about 2 cm wide. The flap is based superiorly. A raw bed for the pharyngeal flap is prepared by dissecting the mucosa from the posterior border of the soft palate for a distance of about 1 cm. The free end of the flap is then sutured with mattress sutures to the nasal surface of the soft palate. The flap tubes itself as it heals, and aids in adequate closure of the palatopharyngeal sphincter. Very definite improvement in speech may be anticipated.

Following operation on children with cleft palate, many require special care to achieve the utmost measure of rehabilitation. Frequent dental examination and filling of cavities in both deciduous and permanent teeth are necessary to avoid extensive caries and formation of dental abscesses.

Orthodontic treatment begun early may be necessary to align irregularly situated teeth properly or to expand narrow dental arches. When palatal tissues have been extensively scarred, prostheses with an extension to partially occlude and aid normal closure of the nasopharynx may be necessary. Secondary adjustment of scars or contour defects of the lip or nose should be performed when the child is old enough so that the maximum permanent improvement in appearance will be obtained. Speech therapy is frequently necessary to obtain the optimum improvement in speech and should be started as soon as the child is 4 or 5 years old.

TRAUMATIC INJURIES OF THE HEAD AND FACE

Intracranial and Facial Injuries

In severe motor accidents and other types of major trauma to the head, it is always important to consider the possibility of intracranial complications, such as cerebral or extradural hemorrhage, cerebral concussion with edema, or contusion and laceration of any part of the brain. Among the signs which should be noted are periods of unconsciousness, either immediate or developing after a lucid period, vomiting; changes in pulse, temperature, and blood pressure; increasing papilledema; and loss or hyperactivity of various reflexes throughout the body. The patient may be restless or become violently disturbed and require restraints. Further signs of severe cerebral injury are indicated by a leakage of cerebrospinal fluid from the nose or of blood and spinal fluid from the ears. If at all possible, the collaboration of a neurosurgeon should be obtained so that intracranial procedures may be carried out if necessary without delay.

With the exception of a terminal condition, there is no contraindication to the taking of roentgenograms, provided reasonable precautions are taken. Morphine, however, should not be given, since it would mask the symptoms essential in diagnosing the patient's condition. At this stage it is usually wise to practice conservative care and to reduce and splint only those fractures which may cause obstruction to respiration or prevent control of hemorrhage. Supportive treatment, careful nursing, and maintenance of a free airway are the trial of care on which a successful outcome of many of these cases depends. After the first 24 hours, signs of meningitis may develop as a result of tears in the dura—usually in the region of the ethmoid bone or frontal sinuses—although basal fractures not infrequently may result in infection in the middle fossa extending through the external auditory meatus. It is important to perform a careful examination of the cranial nerves since medicolegal difficulties may arise should the patient claim injury to any of the cranial nerves following surgical intervention.

Scalp Injuries

Scalp wounds may vary from small lacerations to partial or complete avulsion. In the former group it is usually only necessary to shave the scalp about the wound, after carefully cleansing the margins and deep recesses of the wound. The wound may be closed with interrupted sutures of wire or nylon. The application of a firm pressure dressing will prevent the formation of a hematoma and usually makes stab drainage wounds unnecessary. Deep burns of the scalp may cause bald areas which may be eliminated by repeated partial excision and closure, by undermining or transposition of flaps. Not infrequently, large or small areas of the scalp may be avulsed. These should be treated as soon as possible. When the area is no larger than 2-3" in diameter, it is possible by undermining or shaping of local flaps, to close the defect immediately without undue tension. Closure is facilitated by making relaxing incisions in the galea to permit a more complete stretching of the scalp. On the other hand, in the case of extensive or total avulsion, the pericranium should be cleansed and dermatome skin grafts (0.016-0.018" thick) should be applied without delay. It has been found that by local and general use of antibiotics and scraping of purulent exudate from the surface, it is possible successfully to skin graft wounds of this type up to 48 hours after injury.

Lacerations and Other Injuries

Facial lacerations are very common and their etiologies diverse. Many are due to accidents in the home. Some are the result of industrial accidents, while others occur following crashes of transport vehicles and sporting accidents. Because of their frequency, certain basic principles should be observed, if facial disfigurement or functional deformity resulting from inadequate treatment is to be avoided.

Primary measures following serious facial injuries are control of hemorrhage, maintenance of adequate airway or its provision by tracheostomy, and treatment of shock by transfusion of blood or plasma. The blood supply of the soft tissues of the face is excellent, and there appears to be increased resistance to infection which permits healing even under un-

favorable circumstances. Local anesthetic is most satisfactory in uncomplicated cases. With the advent of new antibiotics, capable of inhibiting a wide spectrum of bacteria, clean-cut lacerations may be closed by primary suture 24 hours after the accident. Tetanus antitoxin or a booster dose of toxoid, if the patient has been actively immunized, should be administered.

Preliminary examination should determine the condition of the *parotid ducts, the branches of the facial nerve, and the possible disturbances of vision*, such as diplopia or interference with ocular movement. Subsequently, the frontal, nasal, zygomatic, maxillary, and mandibular bones should be palpated gently to form an estimate of the extent of the injury.

Wounds of the face fall into various categories. One of the common results of automobile accidents is the presence of *road burns* with deeply imbedded dirt and oil ground into the tissues, which may be removed only by careful scrubbing with a small brush with soap and water or some detergent. Only when the wound appears clean to close inspection should it be dressed with Xeroform gauze and a pressure dressing. Permanent tattoo marks will result if these foreign substances are not removed completely.

Lacerations of the face should be carefully cleansed with soap and water and hydrogen peroxide or aqueous Zephiran. The recesses of the wound should be minutely explored for embedded glass or foreign bodies. In these cases only filamentous epithelial margins or small, jagged edges should be excised since scars are invariably finer when no débridement, as is commonly understood, is carried out. It is useful, in many instances, to excise a small wedge of the dermis on each side of the wound so that when continuous, subcuticular sutures of No. 40 gauge stainless steel wire or Dermalon are inserted in the deepest part of the dermis, the margins of the wound will pout slightly. The epithelial margins of the wound are then carefully approximated with interrupted sutures of wire or Dermalon and tied without tension, this will enhance eversion of the wound edges. These sutures should be removed by the third or fourth day, since the wound is supported by the layer of deep sutures.

Fig 101—*A*, This child was run over by a car and dragged along the road. Photograph, taken on admission to hospital, shows avulsion of most of left eyebrow and part of skin of forehead, with multiple abrasions of the face. Dirt and oil were deeply embedded in the abrasions and lacerations.

B, Emergency treatment included antishock therapy and meticulous removal of all dirt and oil by careful scrubbing with a small sterile toothbrush and soap. A split-thickness skin graft was sutured to the skin defect. Definitive surgery at a later date included reconstruction of the left eyebrow with a full-thickness graft from the scalp and a postauricular skin graft to correct a slight ectropion of the left upper eyelid.

Fig 102—*A*, Patient was struck on head with roller from printing machine which caused concussion, fracture of temporal bone, frontal bone communicating with the frontal sinus, complete separation of malar bone from all bone and soft tissue attachments and contused wound of soft tissues.

B, The frontal bone was replaced, the malar wired to the zygomatic arch and frontal bone, and the wound closed with fine sutures after careful cleansing and minimal excision of soft tissue. Result six months postoperatively. (This patient was treated in conjunction with Dr. Arthur Flaxidge.)

In a kinetic region, it has been shown that a stretching and widening of the scar which often develops gradually over a period of a few months is minimized, since the everted wound edges are first drawn level before the margins can separate to form an unsightly scar.

Lacerations caused by glass are prone to create large *trap-door flaps* with long bevelled thin margins which form a lumpy, elevated flap on healing, due to contracture. This effect may be minimized if as much of the bevelled edges as possible is removed in an effort to convert the injury to that of a simple incised wound. Furthermore, the lengthy use of a

replaced into its normal position and retained with fine interrupted No. 40 gauge sutures. Severed muscle of the lip or cheek should be retained in a similar manner to avoid the creation of a muscular hiatus which will cause a most unpleasant cosmetic defect.

A small defect of the face caused by avulsion of tissue may be repaired by undermining the adjacent tissue with direct suture or by sliding or rotation flaps. A large defect with a vascular bed may be dressed either temporarily or permanently with a free skin graft. If a large portion of the cheek, lip, or nose has been avulsed, the skin and mucosal sur-

Fig. 103—A, Large trap-door flap of cheek with base situated inferiorly. The large metal missile which created the wound also caused a depressed fracture of the malar bone.

B, The depressed zygomatic fracture was elevated directly through the wound, following which careful cleansing and suturing of the wound were performed. Result one year postoperatively.

firm pressure dressing over the flap for 3-4 weeks during the period of fibrotic contraction tends to minimize its tendency to contracture.

Through-and-through wounds involving the ear, lip, cheek, nostril, or eyelid should be approximated, in layers, with the utmost accuracy, and should remain immobilized in a pressure dressing for some time to permit complete healing. The intermediate structures should be approximated with sutures, as well as the mucosa and skin surfaces. For example, cartilage of the nose or ear should be

faces should be sutured to prevent distortion and contracture while definitive treatment is planned.

Occasionally, a portion of the ear, nose, or other feature may be severed completely. If the part can be retrieved and resutured in position within a period of a few hours after injury, there is a fair possibility of the fragment taking as a free graft. Use of a pressure dressing and systemic antibiotic therapy are important adjuncts. If seen early, wounds of the floor of the mouth and tongue may be

sutured primarily. Systemic therapy with antibiotics should be used. If Stensen's duct has been severed and diagnosis is made at the time of the injury, a filiform catheter may be inserted through the duct from the mouth into the severed posterior portion and the cut ends approximated over the catheter with fine sutures. The filiform may be removed in a few days. Chronic fistulas resulting from injury to the parotid gland or duct are most simply and effectively treated by application of a pressure dressing for several weeks and avoidance of a diet and substances during the period of healing which cause marked salivary secretion.

Deep lacerations may cause facial paralysis from severance of the main trunk or branches of the facial nerve. At time of injury an attempt should be made to locate and suture the nerve ends if possible because secondary procedures are more difficult.

Fractures of Facial Bones

These fractures should be immobilized as soon as the condition of the patient permits, since more accurate reduction of the fragments is possible, the patient is more comfortable, and healing without complication is more likely to occur. Laceration of the soft tissues if combined with fractures of the facial bones may greatly simplify reduction of the fracture, following which the soft tissues may be sutured. Comparatively simple operative procedures or methods of splinting suffice in a large proportion of facial fractures.

Nasal Bones.—Fracture of nasal bones usually causes bleeding from the nose, nasal obstruction, ecchymosis of eyelids, and frequently visible deformity. One nasal bone may be depressed, there may be a fracture dislocation of both bones and septum, or the nasal bones and frontal processes of the maxilla may be comminuted and flattened. Simple fractures of the nasal bone may merely require elevation of the bone by means of a rubber-sheathed hemostat within the nose, assisted by external molding with the fingers. When the bone is extensively comminuted and depressed backward between the frontal processes of the maxilla, in addition to elevating the bones and straightening the crumpled septum, it will

usually be necessary to support the bridge by means of two No. 28 gauge wire sutures passed through the nose beneath the fragments from one side to the other. The wires are tied over the lead plates so that the whole acts as a hammock as well as a splint, thus elevating the bridge of the nose and compressing the multiple fragments together.

Zygoma.—An obvious symptom is a flattening of the malar region on the affected side, although subsequent edema may conceal this feature. There may be anesthesia of the upper lip, limitation of movement of the mandible, and diplopia. Fractures of the zygoma may result in a depressed fracture of the zygomatic arch or in the body of the zygoma, or the bone may be extensively comminuted. In the first two varieties the bone may be elevated through a small incision made in the temporal region. A heavy, curved elevator is passed downward, deep to an incision in the temporal fascia, and by an upward prying motion the bone may be raised to correct position. When the bone is comminuted, it is necessary to expose the fragments through an incision in the mouth. An opening is made into the maxillary sinus, and the depressed bone fragments, especially the floor of the orbit, are elevated into normal anatomic position. Then a Kirschner wire is drilled through an intact portion of the zygomatic arch and driven under direct vision beneath the floor of the orbit into the medial wall of the maxillary sinus. This procedure may be supplemented with gauze packing in the maxillary sinuses for a week.

Maxilla.—The most characteristic feature of maxillary fractures is mobility of a segment of the upper teeth or the entire middle third of the face, which is usually elongated. The teeth do not occlude and the patient cannot masticate food. There may be associated fractures of the zygoma and nasal bones, with leakage of cerebrospinal fluid through the nose. The commonly observed types of fracture of the maxilla are fracture of one half of the maxilla, bilateral fracture of the maxillae through the floor of the maxillary sinuses, and pyramidal fracture of the maxillae which usually involves one or both of the zygomatic bones and traverses the nose through the

region of the glabella. The first and second varieties of fractures merely involve placing the upper and lower teeth in correct occlusion after the reduction of the fracture and wiring the jaws together. In these cases much comfort and necessary support will be afforded by a firm bandage which encircles the head and jaw. The pyramidal type of fracture usually involves applying a rather complicated apparatus in which the maxilla is maintained in correct position by means of a Kingsley splint fastened to a plaster headcap by adjustable metal rods or by transverse fixation with Kirschner wires.

the facial bones being blown away together with some of the soft tissues.

The appearance of a patient who has suffered a recent fracture with displacement of the mandible is alarming to those who may not have had much experience with this type of injury, but if a fair number of the patient's maxillary and mandibular teeth are present, there is probably no other bone that may be so simply and accurately replaced following trauma. The maxilla, if intact, forms an exquisitely accurate counter die in which the separated fragments of the mandible and its contained teeth may be interlocked and retained

Fig. 101.—A, The bridge of the nose is crushed and displaced down and backward, forcing the medial canthi apart. Deep lacerations expose the bony fragments and nasal passages.

B, After elevation of the bony fragments and replacement of the fractured septum they are retained by a double wire sling passing through the nose and tied over aluminum plates on each side.

C, Postoperative appearance.

The period of fixation of fractures of the maxilla varies from 3-8 weeks, depending upon the type of fracture and possible complications which may have developed.

Mandible.—Fractures of the mandible are usually classified according to anatomic location and may occur at the symphysis, body, ramus, neck of condyle, or coronoid process. Quite commonly fractures are bilateral, and occasionally three or four separate fractures are present. Gunshot wounds may result in large segments of the mandible or of any of

with eyelet loops or arch bars and intermaxillary wires. It should be noted, moreover, that about 90% of fractures of the mandible fall into this category.

When the lower jaw is edentulous, wires may be carried circumferentially about the mandible with the ends projecting into the mouth so that they can be twisted over the patient's lower denture or a substitute. The simplest way to circumscribe the mandible with wire is to carry one end of the wire down the outside of the mandible close to the periosteum,

and through a (2 mm) incision in the skin with a large, straight abdominal needle; it is then reinserted through the same skin incision and carried up on the inside of the mandible close to the periosteum until it perforates the mucosa on the inner aspect of the alveolar ridge. Pin fixation appliances such as the Roger

Anderson splint or individually molded acrylic splints may be employed when it is necessary to treat the fracture without immobilizing the mandible.

Diet.—When the jaws are wired together, it is necessary to feed the patient a diet of semifluid consistency. It has been found that

even with a complete complement of teeth the patient can manage with little weight loss if a diet of approximately 3,000 ml. of fluid and semifluid substances containing 3,000 calories are taken each day. It is advisable to supplement this diet with Casec or skimmed milk powder and add to the mixture a high multivitamin concentration which may be dissolved in the liquid feedings. Careful oral hygiene measures should be maintained throughout

Anesthetics.—The anesthetic of choice is local, supplemented when necessary in the more complicated fractures by a short period of Pentothal anesthesia. Thus the troublesome complication of vomiting is rarely encountered

Complications.—A tooth in the line of fracture should be preserved even if loose, since

it may prevent displacement of a posterior fragment until sufficient time has elapsed to permit adequate callus to form. At the first sign of development of invasive infection the tooth should be removed. Osteomyelitis is rarely seen if antibiotic therapy has been employed. Adequate drainage should be provided and sequestrum formation awaited before removal is attempted. Nonunion may occur because of malalignment or loss of bone. The bone ends are freshened and wired in proper alignment, or a bone graft may be inserted to replace missing tissue. Trismus may occur as a result of prolonged immobilization of the mandible or from scar tissue formation or bony obstruction. It usually disappears spontaneously, but mechanical dilating appliances may be used if required. Surgical removal of scar tissue or displaced bone fragments may be necessary in some cases. Ankylosis due to intra-articular bony or dense fibrous union may follow a blow on the jaw or a fracture. The condyle may be removed or a segment of bone 1 cm. or more in width is removed across the width of the ramus below the condyle if it is solidly united.

Dislocation.—The usual dislocation is forward and may be unilateral or bilateral. Upward, backward, and forward dislocations may occur but are associated with fracture of the condyle. Forward dislocation may occur by yawning, vomiting, undue use of a mouth gag, or a blow on the chin with the mouth open. Chronic recurring dislocation may occur if the temporomandibular ligaments become relaxed. Diagnosis is made by noting that the mouth is held open and fixed, chewing is impossible, and the condyle may be felt in front of the mandibular fossa, which is empty. In unilateral dislocation the chin is deviated to the opposite side. Treatment consists of lifting the chin with the fingers, while the thumb is protected in gauze are placed on the lower molar teeth, and pressure is exerted downward. A general anesthetic may be necessary, if muscle spasm is present. To prevent recurrence, opening of the jaw may be limited by applying a chin bandage for three weeks or intermaxillary wires which will only permit excursion of a centimeter.

Chapter 11

Neurosurgery

Arthur R. Elvidge, MD

THE SCALP

Much can be learned from an examination of the scalp. In traumatic cases areas of ecchymosis and swelling give information which may be valuable from a diagnostic and from a medicolegal point of view. In a practical sense a severe contusion may indicate underlying fracture. Marked edema may indicate fracture and even rupture of the dura mater. Hemorrhage and edema of the soft extracranial tissues may form a ridge round the edge of an area of contusion which may simulate a depressed skull fracture. This line of swelling can be smoothed out with the examining finger. The crepitation of loose bone fragments can sometimes be palpated.

A contusion in the temporal region should suggest the possibility of an extradural hemorrhage from the middle meningeal artery. Contusion over the general region of the venous sinuses suggests the possibility of subdural hematoma. Discoloration and swelling of the eyelids and periorbital tissues associated with the development of subconjunctival hemorrhage suggests fracturing of the base of the skull. If fracturing is slight, or if it lies at some distance, the discoloration may take a day or more to develop. The subconjunctival hemorrhage generally appears first in the temporal segment. In severe cases it may involve the whole area about the iris. In direct orbital or neighboring injury, periorbital swelling and subconjunctival hemorrhage appear immediately.

Hematomas, excoriations, and lacerations of the scalp hidden by hair may easily be missed, and serious infection results, if neglected. Ecchymosis of the mastoid region usually accompanies a fracturing of the floor of the middle fossa with linear extension into the petrous bone. In this case, bluish discoloration of the eardrum generally develops at once in severe cases, or it may take one or two days to appear if the fracturing is slight or lies at some distance.

Acute infections of the scalp are now uncommon, due to early diagnosis and improved methods of treatment. Swelling about the eyelids may be associated with some neighboring inflammatory or vascular lesion either extracranial or intracranial, such as frontoethmoidal sinusitis, osteomyelitis of the frontal bone, cellulitis of the orbit, epidural or subdural abscess. Periorbital swelling also results from venous congestion in thrombophlebitis and arteriovenous aneurysm.

In nontraumatic cases the general appearance and contour of the scalp is also informative. Sebaceous cysts frequently occur. They may be removed if the patient desires and must be treated when infected. Epidermoid and dermoid tumors call for removal. They may arise in the cranial diploe and there may be intracranial involvement. Cranium bifidum with meningocele or encephalocele will be discussed later under the heading of congenital anomalies. Angiomatous lesions and congenital malformations of the dermis can be treated according to standard methods.

THE CRANIUM

General examination reveals the size, contour, and general shape of the head, the presence of hydrocephalus, craniostenosis, microcephaly, megalcephaly, gross skull defects, irregularities, the relative size of the posterior fossa, and in infants the size of the fontanels and the width of the suture lines. The intracranial pressure can be judged to some extent

Fig 108—Discoloration and swelling of eyelids, subconjunctival hemorrhage, excoriations, and contusion of the side of the head in a case of fracturing of the skull

on palpation over the anterior fontanel. An unusual prominence may indicate the presence of an osteoma or meningioma. Special curiosities of cranial configuration may indicate such conditions as acromegaly or Paget's disease. Auscultation sometimes reveals a bruit which is due to an arteriovenous fistula and occasionally to a large neoplasm.

Roentgenologic examination of the skull reveals the general texture of the bone; congenital lesions, such as cranium bifidum, biparietal foramina, platybasia, and basilar impression, certain changes which result from

Fig 109—Epidermoid cyst of the temporal bone. Lower white area, normal bone; upper white area, epidermoid

increase of intracranial pressure—the beaten silver appearance, enlarged foramina for passing vessels and decalcification of the dorsum sellae, the size and the shape of the sella turcica; disturbances of the endocrine system as in hyperpituitarism; osteomyelitis, tuberculosis,

Fig 112 A. Hydrocephalus in adult B. Acromegaly C. Paget's disease

and syphilis; Paget's disease, eosinophilic granuloma and Schüller-Christian disease, the presence of benign and malignant tumors involving the skull.

In trauma, in addition to the position and type of fracture and the state of the accessory air sinuses, one may derive help from observing the position of the pineal gland and of the choroid plexuses if these are visibly calcified. Occasionally one may find intracranial air, a traumatic encephalogram.

Osteomas may be removed when and if considered necessary by the surgeon, judged on position and rate of growth and desire of the patient. They grow very slowly. Their size can be checked periodically by x-ray. Dermoid cysts should be removed en bloc. Eosinophilic granuloma can be removed. Roentgen therapy alone has been found satisfactory. The invaded bone in the case of a meningiomatous involvement must be resected at the time of removal of the whole tumor. For headache in Paget's disease one can decompress with a bi-subtemporal craniotomy. Encephalocele and meningoencephalocele can be repaired. Osteomyelitis can be cured by block removal including, if necessary, extirpation of the frontoethmoidal accessory air sinuses or mastoidectomy if either constitutes the primary focus. Craniostenosis can be corrected by certain surgical procedures which create artificial suture lines.

THE MENINGES

The meninges are involved in the formation of congenital anomalies as in cranium bifidum and spina bifida with meningocele. The meninges may be involved in infection—acute, subacute, pyogenic, tuberculous, granulomatous, fungiform, and parasitic. Streptococci, staphylococci, and pneumococci meningitis used to be frequently fatal. A few patients recovered from streptococcal meningitis by the use of forced fluids and adequate drainage by lumbar puncture or other means. Pneumococcal meningitis was 100% fatal. Patients with staphylococcal meningitis rarely recovered. Since the employment of chemotherapy and antibiotics the mortality rate, even of pneumococcal meningitis, has been lowered to 30%. In fact, in an otherwise uncomplicated and well-treated case, with eradication of the primary focus, recovery should occur. Even often-repeated daily lumbar punctures seem to be unnecessary except for exact evaluation of progress. At present streptomycin is being used in the treatment of tuberculous meningitis with success. Occasionally one used to encounter pachymeningitis associated with a rapid spread of infection throughout the subdural space. This was invariably fatal.

Sometimes the subdural space may become primarily involved with the formation of a subdural abscess, and occasionally an extradural abscess may be encountered.

The case for subdural abscess has also improved. At one time from 60-100% fatal, the results of treatment have improved from better appreciation of the condition, better surgical treatment, and the antibiotics. Infection in the subdural space, untreated, may spread over the whole central nervous system. It is always localized in the beginning and may remain so, arising from an infected accessory sinus or patch of osteomyelitic bone. Early diagnosis is difficult and important. Focal signs may appear, such as epilepsy, headache, and signs of infection. The onset may be insidious. Treatment is by diagnostic trepanation. If pus is obtained, one anterior and one posterior skull trepanation can be made. The pus is evacuated by suction, and antibiotics are left inside the cavity. Drainage tubing or Penrose drains are suitably placed. These are left in for a variable period of days according to the type of case.

With this combined local and general treatment the mortality rate is greatly reduced.

Extradural abscess must be treated by enlarged skull trepanation, evacuation, drainage, and use of antibiotics. A search for the primary focus of infection must be made and the source eradicated. Osteomyelitis or sinusitis must be dealt with appropriately.

The spaces adjacent to the meninges are of great importance in the pathology of trauma. The problems of subdural effusion and hematoma and of epidural hematoma will be discussed under the appropriate heading. Tumors of the meninges will be discussed under the section on brain tumor.

CEREBROSPINAL FLUID CIRCULATION

The skull is a relatively rigid container, and the brain within is lined and protected by three membranes. The *pia mater*, which carries the blood supply for the cortex, clings to its surface, dipping into all the sulci. The avascular *arachnoid* bridges the small sulci but dips into the major clefts such as the median and horizontal sulci. Primitive mesenchyme separates with the coming of the cerebrospinal fluid into the *pia mater* and the *arachnoid*. The resulting space is known as the *subarachnoid space* and is continuous over the central nervous system. The *dura mater*, the outer tough sheath, is really composed of an inner more elastic and an outer fibrous layer. The *dura mater* clings more or less to the inner table of the skull. It splits along the midline of the skull, and at the level of the tentorium and in the midline of the posterior fossa, to form the medial longitudinal sinus, the lateral sinuses, and the occipital sinuses, respectively. It dips into the median cleft between the cerebral hemispheres as the *falx cerebri* and between the cerebellar hemispheres as the *falx cerebelli* and in the horizontal cleft between the cerebral and the cerebellar hemispheres to form the tentorium cerebelli.

Between the *dura* and *arachnoid* is the subdural space, which normally contains a little yellow fluid. In pathologic states this potential space becomes of great significance as in the case of subdural hematoma and of subdural abscess.

Left and right foramen of Monro

Fig. 113—The ventricular system (Dandy), and subarachnoid spaces through which the cerebrospinal fluid circulates (From Dandy, W. E. *Surgery of the Brain*, Lewis' Practice of Surgery, Hagerstown, Md., 1915, W. F. Prior Co., Inc.)

Fig. 114—Coronal section of the superior sagittal sinus showing relationship with adjacent meninges

Between the dura and the inner table of the skull there are generally some areas with little adherence. In certain injuries it is common for bleeding to occur from the middle meningeal artery and vein, which generally lie in and on the outer layer of dura. Extradural bleeding may strip the dura from the skull and give rise to an expanding extradural clot. Pus from an osteomyelitis may collect in the extradural space. Thus this area under pathologic conditions assumes importance.

The cerebrospinal fluid is formed, few doubt, from the choroid plexuses and is absorbed from the subarachnoid spaces through the vascular bed. Choroid plexus is present in the lateral ventricles. There is a smaller amount in the 3rd and in the 4th ventricle. Both clinical and experimental evidence shows that the fluid formed passes from the ventricular cavities by way of the foramen of Magendie and the foramina of Luschka into the subarachnoid cisternae, and it is thought that much absorption takes place over the surface of the hemispheres.

Under healthy conditions arterial blood enters the cranial cavity at a certain normal pressure, e.g., 1,500 mm of water, and venous blood may leave with a pressure of 100 mm of water.

The intracranial veins must carry a pressure above cerebrospinal pressure, otherwise they would remain collapsed.

The normal cerebrospinal fluid pressure is generally 120-200 mm water, and true normal pressure might be considered to be 150 mm, with the patient lying on his side.

The normal contour of the ventricular and subarachnoid system may be visualized by the injection of air or oxygen into the spinal subarachnoid space or directly into the lateral ventricle. The indications for these procedures are beyond the scope of this summary, suffice it to say that, generally speaking, in cases of high intracranial pressure ventriculography is performed and in other cases encephalography.

If a block occurs in the ventricular system from any cause, be it inflammatory adhesion, congenital atresia of the aqueduct of Sylvius, or tuft of choroid plexus, tumor, parasitic cyst, or abscess, there will arise dilatation of the ventricles proximal to the point of block. The

result is internal hydrocephalus of a noncommunicating variety.

If blockage occurs in the subarachnoid space by adhesions, plastic exudate, diffuse neoplasia, or hemorrhage, dilatation will occur not only of the ventricles but also of the subarachnoid cisternae posterior or proximal to the point of block. This is known as a communicating type of hydrocephalus.

If an expanding lesion arises in the brain it will cause distortion of the ventricular system and may cause some obliteration of subarachnoid markings, which may be seen in the ventriculogram.

If a contracting lesion or atrophic lesion is present, a passive increase in size of the ventricles and spaces may occur, and sometimes areas of focal dilatation of a ventricle give rise to an appearance of traction of a portion of the ventricle, called by Foerster and Penfield "ventricular wandering."

In cases of high intracranial pressure lumbar puncture can be a source of great danger. The pressure is released below but the intracranial pressure forces the brain into the foramen magnum, causing herniation of the cerebellar tonsils which may result in strangulation of the blood supply to the medullary centers and death. In the case of a lesion above the tentorium a second mechanism comes into operation. The uncinate gyrus of the temporal lobe may be crowded into the incisura tentorii adjacent to the cerebral pedicle, compressing the ipsilateral 3rd cranial nerve and even the posterior cerebral artery. The opposite or both cerebral peduncles may be notched against the sharp edge of the tentorium. Serious signs will arise from this type of herniation which include deepening coma, 3rd nerve paralysis, decerebrate rigidity, and hemiplegia, which in 10% of cases may be ipsilateral and may be to some extent bilateral.

Compression of the 3rd cranial nerve causes dilatation and fixation of the ipsilateral pupil. This is sometimes bilateral in terminal stages. Infarction of the occipital lobe from compression of the posterior cerebral artery and infarction of the brain stem may occur as late phenomena preceding death. These mechanisms operate in cases of high intracranial pressure. They are, on occasion, brought to acute fulfillment by lumbar puncture.

SYMPTOMATOLOGY

Symptoms and signs may be briefly discussed under two headings

1. General symptoms and signs of increased intracranial pressure
2. Focal signs

General Symptoms and Signs of Increased Intracranial Pressure

Headache may be generalized, bioccipital, bifrontal, severe, and tending to become continuous. It varies to some extent with posture. Some believe that the headache is more severe in the morning. In final stages it is violent. Even raising the head from the pillow may accentuate it. In the rare case of a ball valve block at the neck of a ventricle, change of head posture may relieve or accentuate the headache. The history must be carefully taken to differentiate headache from other causes, e.g., migraine, arterial hypertension, trauma, psychosis, low intracranial pressure, hypoglycemia, sinus disease, or eyestrain.

Vomiting is due to a disturbance of centers in the medulla, probably on a vascular basis due to pressure anemia.

Papilledema is present in the majority of cases of expanding lesions which have raised the intracranial pressure, although in many cases it is absent. Blurring of the edges of the disc first occurs on the nasal side and may rapidly invade the whole edge. Swelling generally develops in the same order and eventually the normal cup becomes a swollen convex surface. Hemorrhages and exudate often appear relatively late or not at all in these cases of increased intracranial pressure. In arterial hypertension one generally sees more widespread patches of exudate and hemorrhage for the degree of papilledema present.

Clinically during this time the blind spot enlarges and the visual fields become constricted and visual acuity eventually diminished. If the pressure is removed, recovery, good or relative, will occur. If allowed to continue, blindness will ensue. Sometimes when intermittent fluctuations of intracranial pressure occur, transient blackouts may be premonitory signals of increasing intracranial pressure.

In cerebral lesions the papilledema may be greater on the side of the lesion, and papille-

dema does not always occur. In lesions of a frontal lobe near the optic nerve, direct pressure may be exerted upon it, giving a primary type of atrophy with pallor, while papilledema may be present in the opposite nerve head from the general rise of intracranial pressure, the Foster Kennedy syndrome. The mechanism is considered to be due to blockage of the sub-arachnoid space around the nerve or pressure on the central retinal vein as it crosses it. The result is swelling of neurofibrils and their eventual destruction unless intracranial pressure is relieved in time.

Papilledema generally develops in a matter of days, weeks, or months but can occur in a matter of hours. Expanding lesions in the posterior fossa do not always give papilledema, on the contrary, pallor may occur.

Signs of acute increase of intracranial pressure may or may not include all or any of the above. In addition, there are some signs that are very characteristic of acute compression and such occur in varying degrees. They are of very great importance in head injury and are described again under that heading.

Third nerve paralysis with progressive and rather rapid dilatation of the pupil and loss of the light reflex on the side of the lesion, often associated with some degree of extrinsic ocular paralysis, is believed to result from herniation of the hippocampal gyrus over the free edge of the tentorium which compresses the oculomotor nerve. In late cases the posterior cerebral artery may be occluded, giving infarction. In addition, a similar sequence of events may follow on the opposite side.

The pulse is generally slowed by acute rises of intracranial pressure and the pulse pressure widened with increase of systolic and some lowering of diastolic pressure. This is no doubt an effect on the medullary centers, as are also vomiting and hiccoughs.

Drowsiness and unconsciousness are signs of compression. Yawning is said to be a sign of a lesion within the 3rd ventricle. Rubbing of the nose has been given a similar significance. The respiratory rhythm may be affected in increased intracranial pressure. In severe cases this may lead to Cheyne-Stokes rhythm and finally cessation of respiration. Pressure on the medulla readily causes cessation of respiration, and the slightest manipulation of the lower

brain stem will cause a variation in rhythm. A rapid, stimulated, but regular respiratory rate occurs in certain types of upper brain stem or diencephalic involvement.

Herniation at the level of the incisura tentorii may cause some compression of the cerebral peduncles against the edge of the tentorium and thus give rise to various degrees of corticospinal tract involvement, including hemiparesis, spasticity, and reflex changes. In some cases the paralysis is on the ipsilateral side which is due to notching of the opposite cerebral pedicle. Frequently there is some involvement of both sides and a tendency toward decerebrate rigidity. Herniation of the cerebellar tonsils through the foramen magnum

upon the physiology of the particular areas involved.

The frontal lobe is that portion of the cerebral hemisphere which lies in front of the fissure of Rolando. Lesions of the frontal lobe are likely to be associated with various mental and behavioral disturbances which may be obvious or may be so slight as to pass recognition. Lack of initiative, concentration, and impaired judgment, *laissez-faire* attitude, slovenly habits, loss of ethical standards, and moral impairment have been described. These disturbances also may accompany a temporal lobe lesion. It is thought that such symptoms are more severe when the lesion involves the dominant hemisphere.

Fig. 115—Localization of certain lesions in the cerebral hemispheres which produce obvious disturbance of function (After Penfield and McEachern, 1938)

also occurs as a result of increased intracranial pressure. In the extreme this results in death as a result of involvement of the respiratory center.

Focal Signs

Focal signs must be assessed on the basis of the anatomy and the physiology of the brain. A full description of typical syndromes would require considerable space and is beyond the scope of this chapter. However, one may work out many possible combinations of symptoms and signs by taking cognizance of simple anatomic and physiologic data.

Localization can generally be made upon accurate history and clinical examination. Focal signs are produced by the local compression or disturbance of the lesion. They will depend

upon the size of the lesion and its position relative to the motor cortex. Thus a lesion anterior to the motor cortex in the parasagittal region will give maximal disturbance in the foot, whereas one in the fissure of Sylvius will give most change in the face and speech mechanism.

In the dominant hemisphere motor speech seems to be subserved by an area immediately above the fissure of Sylvius and anterior to the motor cortex in the posterior portions of the inferior frontal gyrus, where it is subdivided by the two anterior rami of the lateral sulcus, forming the *pars triangularis*. A lesion in this general area will give rise to a disturbance in

speech in which the patient understands and may even know what he wants to say but cannot utter the words. When this is on an intellectual level it is called motor aphasia or expressive aphasia. This is to be differentiated from dysarthria, which consists of an inability to execute the movements necessary for normal articulation.

Generally, disturbances of speech are of a mixed type and difficult of anything but the simplest analysis. It must also be realized that much of the speech mechanism must lie beneath the cortex.

cur from lesions of certain areas on the under-surface of the frontal lobe. Disturbances of autonomic function are thought to arise from lesions of the frontal lobe.

The parietal lobe is bounded in front by the fissure of Rolando, posteriorly by the parieto-occipital fissure, and below by the fissure of Sylvius. It contains the postcentral convolution which includes cell stations for discriminatory or deep cortical sensation. Lesions in the parietal lobe which encroach on or disturb this convolution cause loss of discriminatory sense from muscles and tendons

Fig 116—Motor and sensory sequences along the fissure of Rolando (After Penfield and Boldrey, 1937)

Stimulation of the brain at certain points in front of the motor cortex in the second frontal convolution provokes conjugate eye turning to the opposite side. Sometimes one encounters an irritative lesion, which causes the eyes to be rotated to the opposite side, and rarely a paralytic lesion, which allows them to swing to the side of the lesion, presumably from relative overstimulation from the opposite side. In an epileptic seizure this is more commonly seen in the phase of exhaustion. It is known that other areas of the cortex, when stimulated, will cause deviation of the eyes to the opposite side. Irritability and hyperactivity are thought to oc-

cur from sensory receptors in the skin, all of which can be tested practically by testing for sense of position and two-point discrimination. Such other tests, as for the recognition of texture and weight, can be added.

The parietal lobe contains other functions which have to do with the elaboration of receptive mechanisms, but these are not well understood. Astereognosis falls into this category.

Along the upper margin of the fissure of Sylvius there are probably centers which have to do with speech, and the author feels that when this area is involved the principal dis-

turbance is one of impaired memory for words, giving rise to degrees of anomia. In addition, lack of understanding is also evident.

Disease in the region of the angular gyrus produces a disturbance of reading, alexia, and of writing, agraphia, which is part of the speech mechanism.

Lesions deep in this region may cause degrees of pressure upon a segment of the optic radiation. This results in a lower quadrantic field defect on the opposite side.

The occipital lobe lies posterior to the parieto-occipital fissure and contains the calcarine cortex. Lesions here produce homonymous hemianopia to the opposite side, lesions above the calcarine fissure cause a homonymous

in the temporal lobe beginning 5 cm. posterior to the tip. No speech representation is found in the first, second or third convolution anterior to this and speech representation seems to be more in the second temporal convolution. However, it is impossible to distinguish between first and second in this area." Regarding the function of olfaction, hearing, and memory, the reader must be referred to standard works on physiology and current literature.

Many patients with cerebral disease suffer convulsive seizures. The seizure itself may be of localizing value. Thus a seizure arising in one frontal lobe may start with the head and eyes turning to the opposite side, followed by jerking of the contralateral arm and leg and

Fig. 117—Common initial phenomena in epileptic seizures arising in different areas of the brain (After Penfield and McEachern, 1938)

quadrantic hemianopia below and to the opposite side; and lesions below the fissure quadrantic homonymous field cause defects above the horizontal. Lesions posterior to the lateral geniculate body may show sparing of macular or central vision.

The nondominant temporal lobe seems to be relatively silent, but on the dominant side the first temporal convolution contains certain connections for speech which is generally severely disturbed in lesions of this region. The patient can utter words and phrases, but they are meaningless and confused. This is sometimes referred to as a jargon aphasia. It has been stated by Penfield that "speech is located

loss of consciousness. Discharges further anterior can give rise to turning of the head followed by rotation of the trunk.

A lesion adjacent to the motor cortex may cause clonic movements in the appropriate limb. The discharge generally spreads to neighboring areas, giving rise to a Jacksonian march. Speech becomes involved if the dominant hemisphere is affected.

The accurate description of the march of events in a seizure determines its value in localization. In this the recognition of an aura is all-important. Auras may consist of a sensation rising from the epigastrium, numbness of a limb, an olfactory, gustatory, visual, or audi-

tory hallucination, according to location. For example, an attack arising in the parietal cortex may commence with numbness of the arm, with clonic movements following as the wave passes forward. An aura of twinkling lights may be described from a lesion in the posterior parietal region. Attacks from the occipital lobe may precipitate transient hemianopia. Dizziness is a frequent aura in lesions of the temporal lobe. Micropsia and macropsia are described and occasionally auditory hallucinations. Sometimes a past event will reappear in the patient's mind, "déjà vu" phenomenon. Autonomic phenomena may be observed in lesions of the diencephalon.

Lesions in the neighborhood of the 3rd ventricle which involve the thalami cause hypesthesia or paresthesia of the contralateral side of the body. As the internal capsule is affected there are various degrees of hemiparesis.

If the hypothalamus is involved diabetes insipidus becomes a feature. Autonomic disturbances with changes in pulse rate and blood pressure are sometimes found. Occasionally in an expanding lesion one encounters changes in the visual fields from involvement of the neighboring optic tracts. If convulsions occur they cause flushing of the face and neck, sweating, rise in blood pressure, and alteration of pulse rate.

Expanding lesions within the 3rd ventricle cause blockage of the cerebrospinal fluid, with resulting dilatation of the ventricular system proximal to the lesion. There may be few objective signs except papilledema, and the patient experiences severe headache which may be intermittent if the lesion is of a ball-valve type.

Lesions in the midbrain give rise to various degrees of ocular paresis with pupillary changes, large pupils, sometimes small and unequal pupils, impaired reflex reactions and failure of conjugate upward eye movement may be observed. Blockage at the aqueduct of Sylvius causes internal hydrocephalus. In neoplasms of the pineal gland puberty praecox is described.

Lesions of the cerebellar hemispheres generally cause incoordination of the movements of the ipsilateral extremities. Hypotonia with

reduced reflexes is typical. Nystagmus is frequent in cerebellar lesions and is usually greater on gaze to the side of the lesion. Lesions of the vermis cause severe trunkal ataxia and rombergism.

Associated compression of the brain stem produces hypertonicity with increase of deep reflexes from involvement of motor tracts. Lesions of the pons and the medulla oblongata involve cranial nerve nuclei and various combinations of involvement of the long tracts. Hiccoughs, vomiting, and severe disturbances of respiration are likely to occur.

If blockage of the 4th ventricle occurs, internal hydrocephalus results with symptoms of increased intracranial pressure. Headache is severe and there may be few signs.

Tumors involving the coverings of the brain cause neurologic focal signs by local compression of the brain. For example, a parasagittal meningioma may compress the midline sensorimotor cortex, causing characteristic signs. Among other symptoms and signs a meningioma of the lesser wing of the sphenoid bone may cause compression atrophy of the adjacent optic nerve and, in addition, pain referred to the area supplied by the first division of the 5th cranial nerve.

An expanding lesion in the cerebellopontine angle, e.g., a perineurial fibroblastoma of the acoustic nerve, causes paralysis of the 8th and the 7th, often the 5th, and sometimes the 9th, 10th, and 11th cranial nerves, as well as signs of cerebellar and brain stem involvement.

It may be added that there do seem to be sites of predilection for tumors with characteristic signs, but these are too many to list in detail.

HEAD INJURY

The subject of head injuries can be discussed under the following headings:

I Injuries of the Brain

- 1 Cerebral concussion
- 2 Cerebral contusion
- 3 Cerebral laceration
- 4 Cerebral compression
- 5 Cerebral edema

II Traumatic Intracranial Hemorrhage

- 1 Subarachnoid hemorrhage
- 2 Subdural hemorrhage

3. Epidural hemorrhage
4. Intracerebral hemorrhage
5. Subpial hemorrhage

III Fractures of the Skull

1. Linear fracture of the vault
2. Linear fracture of the base
3. Depressed fracture, simple
4. Depressed fracture, compound

IV. Complications, Early and Late, From Intracranial Injury

1. Meningitis
2. Osteomyelitis
3. Brain abscess
4. Post-traumatic headache
5. Post-traumatic dizziness
6. Facial paralysis
7. Post traumatic epilepsy

Injuries of the Brain

Cerebral Concussion.—From a practical point of view cerebral concussion may be defined as a transient lapse of consciousness or as memory loss following immediately upon an adequate blow to the head, without obvious pathologic findings. Because the lapse of consciousness in pure cerebral concussion is brief, it has been difficult in a clinical way to demonstrate any particular characteristic phenomena associated with it; however, recent researches have brought forth some interesting facts which give rise to further speculation.

Denny-Brown and Russell in 1941 published an account on experimental cerebral concussion in the cat and in the macaque in which they studied the effect of concussive blows with the aid of a pendulum. They found that concussion was more easily produced when the head was free than when supported on a hard surface. From this experience they coined the terms acceleration concussion and compression concussion. They found that acceleration concussion in the monkey and cat could be produced by a heavy mass with a velocity of 28.3 feet per second and the energy transmitted, 17.83 foot pounds. Following the concussive blow there was an interference with brain stem reflexes for about 90 seconds which might terminate in death or recovery within five minutes. They concluded that experimental concussion results in the following typical phenomena:

1. Loss of corneal reflex, the most important sign

2. Loss of the pinna reflex, which consists of any flicking movement of the ear, shaking of the head, or scratching with the hind limb, from a stimulus applied to the inner pinna.

3. A sharp rise of blood pressure, not constant

4. Lasting inspiratory spasms only with light anesthesia.

5. An initial jerk in the musculature followed by delayed spasms, and then loss of postural tone. They are abolished by deep anesthesia.

They concluded that death from concussion results from a variety of traumatic primary shock. The primary shock is associated with and proportional to effects which suggested a stimulation of the vagoglossopharyngeal system in the medulla.

In 1944 Walker, et al. made a study of the physiologic basis of concussion by the method of falling weights. They noted that concussion in the cat under Vinethene-Novocain anesthesia is frequently associated with an attack, tonic and clonic. In the monkey, seizures consisted of a tonic phase and were less common. The authors interpret the attacks as an intense stimulation of the nervous system. Changes in respiration and circulation may occur. Usually there is a respiratory gasp followed by irregular respiration, or apnea. Usually a rise of blood pressure occurs at once or a few seconds after the blow, due to an effect upon the brain stem, thus giving evidence of intense stimulation of vasomotor centers leading to peripheral vasoconstriction. They noted sometimes slowing of the pulse due to vagus excitation. Abolition of reflexes occurred only if the spinal cord was intact. These authors believed that intense stimulation of the cerebral cortex and brain stem produces excitation at the moment of the concussive blow, and that this is not due to any alteration in circulation, oxygenation, metabolism, or acid-base regulation of the cerebral cortex because it occurs within a fraction of a second and before such alteration can take place.

In 1916 Windle, et al. found a slight increase of water content 8-17 hours after experimental concussion in animals.

Electrical changes were studied in experimental concussion by Williams and Denny-Brown in 1941. They found that concussion

was associated with "diminution or cessation of the electrical activity of the whole cerebral hemispheres." They observed a delayed appearance of abnormally slow waves which they felt might represent a stage in recovery from concussion. They concluded that concussion was the direct result of mechanical violence to cerebral cells and was not dependent upon secondary changes such as "edema, anoxia, hypoglycemia for its initiation."

Dow, et al (1945) examined electroencephalograms in patients with head trauma who were employed in shipyards. They examined 213 patients, and in 71, electroencephalograms were taken within 30-60 minutes after the accident. They estimated the velocity attained at the moment of impact in split seconds and determined the force involved. The percentage of abnormal records was slightly greater in patients examined within 30 minutes. Rapid disappearance of abnormal electroencephalographic findings, they felt, pointed to a mechanism in concussion other than petechial hemorrhage or contusion. The forces at impact were of the same order as those found by others to produce experimental concussion. Patients who had to stay off work more than 24 hours showed a greater percentage of abnormal records and a more severe injury as judged clinically, but the electroencephalographic records they found less reliable. They felt that there was a difference in susceptibility to electroencephalographic changes in different individuals on the basis of a few observations; also, they did not feel that there was any particular activity that seemed characteristic of the electroencephalogram following mild trauma.

Jasper, et al (1940) found that the electroencephalogram was the most sensitive indicator of cerebral injury and provided a sensitive objective measure of recovery. Electroencephalographic changes found were listed as follows:

1. Random or regular delta waves varying in frequency from less than one to six per second
2. Poor regulation or disorganization of the alpha rhythm
3. Epileptiform discharges

In some cases of severe injury, delta and epileptiform waves and disorganized activity were observed in the electroencephalogram several years after the injury. These were associated clinically with changes in personality, seizures, irritability, disorders of thinking, and, in a few instances, with no remarkable clinical abnormality. Post-traumatic syndromes due to malingering or hysteria were clearly evident since in these none of the characteristic abnormalities associated with genuine head trauma were obtained. The electroencephalogram provides an extra tool in the differential diagnosis of subdural hematoma and effusion, epidural hematoma and intracerebral hemorrhage, and focal and general trauma. According to Jasper, et al. (1943), the more severe the brain injury, the more complete is the disappearance of alpha rhythm and slowing of the delta frequency, and the electroencephalogram would appear to be a more sensitive measure of cerebral damage than routine clinical estimate. It was found that amnesia and confusion, irritability, and drowsiness without loss of consciousness were just as important as the history of unconsciousness in indicating the severity of cerebral damage shown by the persistent electroencephalographic abnormality during the first 10 days. It was found that in skull fracture severe electrical changes are more likely to be persistent and, also in cases with blood in the cerebrospinal fluid, are more likely to show persistent and severe changes, and, further more, in the presence of abnormal neurologic signs immediately after the injury, are associated with more severe and persistent electrical changes during the first 10 days. In cases with increased cerebrospinal fluid pressure there was usually more severe abnormality. Young patients seemed to be more vulnerable from the electroencephalographic point of view. The electroencephalogram might return to normal within 24 hours after concussion with loss of consciousness. It was concluded, however, that records taken after the first day and up to 10 days following the injury provided a more reliable picture of residual damage to cerebral tissue and were of greater diagnostic and prognostic value. A normal or mild change in the electroen-

Fig 118—Severe contusion of the brain

Fig 119 Contusion or infarction of the brain stem.

cephalogram provides a useful additional guide to the management of convalescence. Local electroencephalographic abnormality may persist for years and may develop into focal epileptiform discharges associated with areas of degenerating nerve tissue. If the nervous tissue is completely destroyed the electroencephalogram should be normal. Such an area may be seen, however, by pneumography. Minor epileptiform discharges may be seen without clinical seizures but may be accompanied by other symptoms. The electroencephalogram may aid in the diagnosis of intracerebral and extracerebral hemorrhage. It is not

a substitute for careful clinical study of the patient but in conjunction with it makes a valuable contribution.

Cerebral Contusion.—The term cerebral contusion as used in the present instance signifies merely a bruising of the brain. This may be from the effect of the direct blow and may include so-called contrecoup lesions. Contrecoup lesions apparently occur as a result of the skull moving when struck. According to the hypothesis of Holbourn (1944) cerebral contusion and contrecoup can be explained upon the basis of rotary acceleration. The ex

Fig. 120.—Brain waves Electroencephalogram

Typical electroencephalograms showing the changes which occur after head injury, arranged in order of severity. N is a normal record, +++++ is the most severe type of disturbance with marked depression of cortical activity. The intermediary stages are gradual and often overlap. The characteristic frequencies for each type are shown above. (From Jasper, Kerhman and Flidge, A. Research Nerv. & Ment. Dis., Proc., 1943, 24: 389-420, 1945.)

periments of Pudenz and Shelden (1946) afford some evidence for this. The mechanism for contrecoup still seems to be very controversial and is obviously partly a function of the inertia of the brain. Very extensive contusion of the brain, such as that seen in the temporal lobe, which has recently passed under the caption "explosion of the temporal lobe" (Botterell) may give rise to considerable cerebral compression due to concomitant cerebral edema.

Cerebral Laceration.—The term laceration simply means a tear in the continuity of the brain substance. This may occur as a result of a depressed fracture or as a gunshot injury and can be diagnosed only by exposure.

Cerebral Compression.—A pathologic degree of cerebral compression may be brought about by intracerebral epidural and subdural hematomas, subdural effusion, and massive cerebral contusion with cerebral edema. The usual signs of acute cerebral compression include increasing drowsiness, slowing of the pulse, widening of the pulse pressure, changes in respiration, progressive dilatation and fixation to light of the ipsilateral pupil, and finally extensor rigidity of varying degree with plantar extension and stiff neck. Homonymous hemianopia may occur as part of the process. Hemiplegia is usually present as a focal sign of the primary lesion.

Two extremely important mechanisms operate in cases of marked increase of intracranial pressure, apart from the focal compression produced by the lesion in a particular case.

1 *Herniation of the brain at the incisura tentorii* is characterized by a herniation of the hippocampal gyrus over the free edge of the tentorium due to an ipsilateral expanding lesion. This causes pressure on the adjacent 3rd nerve, which results in various degrees of paralysis of the oculomotor nerve, commencing usually with progressive enlargement of the pupil and fixation to light. Reid and Cone (1939) found that extradural compression in monkeys would cause an ipsilateral pupillary dilatation which would return to normal on release of pressure. The fixed pupil, they believed, was an early sign of cerebral herniation at the incisura tentorii. Fischer-

Brugge (1951) has brought forth evidence to show that the syndrome is brought about by compression of the 3rd nerve against the edge of the clivus. Reid and Cone (1939) also confirmed the observation of Meyer that associated infarction of the ipsilateral occipital lobe might occur as a result of occlusion of the posterior cerebral artery. In severe cases, the posterior cerebral artery may be compressed, with resulting hemianopia. In some cases, notching of the opposite cerebral peduncle against the free edge of the tentorium occurs to the extent that an ipsilateral hemiplegia is produced (Kernohan and Waltman).

2 *Herniation of the brain at the foramen magnum* consists of a forcing down of the cerebellar tonsils into the foramen magnum. This wedging causes compression of the medulla oblongata with disturbance of vital centers, causing alterations in pulse and blood pressure and early cessation of respiration. Abundance of mucus from the respiratory tubes is common.

Decerebrate rigidity with tonic seizures is due to a lesion or disturbance of the brain stem lying between the red nucleus and the acoustic striations. It may result from ischemia, probably from compression of the basilar artery and its branches.

Cerebral Edema.—This is the most feared complication in head injury and seems to be generally associated with massive cerebral contusion. If such an area of contusion consists of completely destroyed brain, and if such an area of contusion is sufficiently well localized and confined to relatively unimportant parts, the best result may be obtained with a débridement of the destroyed brain. Hypertonic solutions and subtemporal decompression alone are generally completely ineffectual.

Treatment

Cerebral Concussion.—Modern tendency has been to treat cases of simple cerebral concussion with a minimal amount of bed rest. This will be graded according to the duration of unconsciousness and duration of confusional disturbance or memory loss. Usually the patient remains in bed 2-5 days. It is generally felt that the sooner the patient can be rehabilitated and sent back to work, the better.

His case, of course, should be properly evaluated as soon as possible after the injury, and he should be given a clear understanding as to the diagnosis and the length of time that he will probably be off work.

Cerebral Contusion and Laceration.—The treatment of cerebral contusion will be very much the same as that for concussion, except that the more severe cases with neurologic signs will require longer hospitalization. Cerebral laceration is generally combined with depressed skull fracture or gunshot injury. Débridement of devitalized brain must be carried out at the time of elevation of the depressed fracture. The treatment of cerebral compression will resolve itself largely into the question of diagnosis and removal of the cause where that is possible.

Special Tests

X-rays of the skull should be obtained in all cases of head injury. It is safer for all patients with concussion and, of course, more severe injuries, to be hospitalized, especially for the first 24 hours. The electroencephalogram is of considerable interest in the diagnosis and prognosis. Lumbar puncture is of value in demonstrating blood in the cerebrospinal fluid, which gives some indication of the degree and type of injury but is of greater use in estimating increase of intracranial pressure when that is necessary. The tendency is to do few lumbar punctures and to limit their use to the special indications in diagnosis and treatment suggested by continued headache.

Traumatic Intracranial Hemorrhage

Subarachnoid Hemorrhage.—This merely signifies that sufficient injury has taken place to cause bleeding into the subarachnoid space. This, in itself, may not be particularly serious.

The principal sign is stiff neck. It can be diagnosed by lumbar puncture, which probably should be done in the more severe injuries in any case. This gives some idea of the severity of the injury but is only one point in the evaluation of the case. Frequent lumbar punctures to eliminate the blood are unnecessary, and it was shown by Sprong (1934)

that very little blood is removed by this method. However, less post-traumatic headache is encountered when the patient has had a combination of adequate bed rest and lumbar puncture, nevertheless, the general trend is to omit lumbar puncture unless specific information is desired. The general management of the patient, both physically and psychologically, is all-important.

Subdural Hemorrhage.—The diagnosis and treatment of subdural hemorrhage is often difficult, though superficially it would appear simple. It must be suspected from the history, the nature of the injury, and the clinical examination. Symptoms may develop rapidly with signs of increasing intracranial pressure, drowsiness, coma, stiffness of neck, hemiparesis, plantar extension, dilated pupil, pulse and blood pressure changes, or slowly, as an expanding lesion with headache. X-rays may show a shift of the pineal gland or of the choroid plexus if calcified. Ventriculography may be advisable. The final proof, of course, is in seeing the hematoma.

One may puncture the skull with a twist drill according to the technique of Cone. The dura can be opened simultaneously with the drill or with a needle. With a small brain needle the depth of the epidural and subdural spaces can be estimated and in many cases an epidural or a subdural hematoma recognized. If a fluid effusion is present under pressure, the measure may even be lifesaving. Strategically placed burr holes through which one can inspect the subdural space may be preferable. They must be suitably placed to discover the clot. It generally lies over the convexity of the hemisphere but may lie toward the base. Usually biparietal or bitemporal openings suffice. A Penrose drain can be left in the subdural space and brought out through a separate wound. If the subdural hemorrhage is of clotted blood or of long standing with membrane formation, and especially if an inner membrane is formed, it is better policy to turn a reasonably sized bone flap and remove the membranes completely. It is important, of course, to consider both sides in dealing with subdural hemorrhage, as frequently they are bilateral.

Epidural Hemorrhage.—This is diagnosed again on the basis of history, examination,

Fig. 121—Case of chronic subdural hematoma, with membrane formation

A, Initial incision of dura, leaving partial attachments at the corners or at the crossing of the middle meningeal arteries

B, Bulging of the outer membrane of the hematoma upon section of the dural attachment

C, Reflection of dura and exposure of the outer membrane of the hematoma

D, Outer membrane already partially removed and semifluid portion of the hematoma partially evacuated. Note hook lifting inner membrane away from the arachnoid. Entire membrane is removed in continuation of operation

progress, and x-ray. A head injury followed by loss of consciousness, a so-called lucid interval and a relapse into a state of coma with hemiparesis as a focal sign and ipsilateral 3rd nerve involvement is typical. An infinite number of variations occurs but the condition can usually be diagnosed on clinical grounds alone. In some cases the acuteness of the compression will be so extreme that the patient will have to be operated upon immediately in order to save his life. On the other hand, gradually increasing drowsiness may be the important factor. One can again choose the method of Cone, with

If there is unnecessary delay or postponement, the brain pressure will cause death from cerebral herniation and irreparable brain stem damage.

Intracerebral Hemorrhage.—If a sizeable intracerebral hemorrhage is demonstrated, it can be removed in part by aspiration or more completely by open operation. This type of lesion is not uncommon. It may be suspected on clinical grounds and verified by ventriculography.

Subpial Hemorrhage.—This need hardly be mentioned but does occur. It is seen during

Fig 122—Case of epidural hematoma after removal. A small, free bone flap has been turned on the fracture line to permit evacuation of the clot. Note drain in lower left trephine hole. Bone has been wired back into place.

a twist drill to verify the diagnosis. This is somewhat quicker than waiting for x-rays, etc. This procedure is used only if one is certain that the intracranial pressure is above normal, which tends to ensure against bleeding from any vessels that are encountered as a result of the tamponading effect of the brain against the dura. When calcified, the position of the pineal gland should be observed by x-ray and the course of the fracture, if one is present. When the diagnosis is sufficiently clear it is essential to do an immediate subtemporal craniotomy and evacuate the clot

intracranial operation and occurs as a result of trauma. It has no particular significance unless it acts as an early or late cortical irritant.

Fractures of the Skull

Linear Fracture of the Vault.—The position of the fracture and its extent will afford some idea of the type of complication to be expected. A fracture over one of the major blood sinuses may be associated with subdural bleeding; if over the temporal region, with epidural hematoma. If a fracture involves the accessory air sinuses, the question of infection

Fig 123—X-ray of basal skull fracture showing intracranial gas

has to be considered. Ingress of air into the cranial cavity may even occur. The extent of fracturing gives some idea of the force of the injury which will help one in the determination of prognosis and the length of treatment. The skull should be x-rayed in all cases of head injuries.

Linear Fracture of the Base.—The patient with a basal skull fracture will, generally speaking, need a longer period of bed rest. There may be associated contusions of the brain and involvement of cranial nerves. The line of fracture frequently crosses the petrous bone to involve the mastoid air cells, with the

risk of infection. Fractures often enter the frontal, ethmoidal, and sphenoidal accessory air sinuses. A leak of cerebrospinal fluid from the ear or from the nasopharynx is common. Prophylactic treatment with suitable antibiotics or chemotherapy is indicated, but meningitis may still occur. It is important to advise the patient not to sneeze forcibly or blow his nose in the presence of a cerebrospinal fluid leak from the nose. He should in that instance open his mouth widely and relax. A semi-Fowler's position is probably helpful. For a leak through the ear, it is probably wisest to do no more than cover the ear with clean dressing on the outside. Some prefer to instill a suitable antibiotic into the ear canal. Most leaks stop in the first 2-3 days. Occasionally there is a recurrence. The leak may call for operative repair. A very free and dangerous cerebrospinal fluid leak into the nasopharynx is frequently associated with a so-called pyramidal fracture in which the facial bones have become severed from the base of the skull. This is common as a result of crashes by airplane and automobile dashboard injuries. In this type of case one must arrange a splinting device to fix the facial bones to the skull, this can best be carried out by the oral surgeon. For certain difficult cases a method of employing a modified Roger Anderson splint applied to the skull has been described by Elvidge and Baxter (1944), which eliminates the necessity for fixation to a plaster cap.

Depressed Fracture, Simple.—In the case of a simple depressed fracture it is routine to elevate the fragments unless the depression

Fig 124 Roger Anderson splint used in case of multiple facial fractures

is very shallow and situated over a silent area of the brain. It is not urgent to reduce this in the first few hours, but it is probably wiser to elevate it within a day or two. It is advisable to make a small opening in the dura to inspect for the presence of subdural hematoma or effusion. Contused brain in the area of a laceration may be débrided suitably.

Depressed Fracture, Compound.—In this instance where the depressed fracture is covered by a laceration of the scalp, the earliest possible débridement of the wound and elevation of the depression is required. Softened brain tissue is débrided when this is irrevocably damaged and often herniated.

Fig. 125.—Case of untreated compound depressed skull fracture, showing cerebral herniation covered by dirty, infected granulations and requiring prolonged period of dressings and plastic surgery.

Scalp Laceration.—It is of the utmost importance that scalp lacerations be débrided, cleansed, and properly explored lest foreign bodies or a depressed fracture be overlooked. The hair must be shaved generously about the wound, and if, in the male, the wound is extensive, the whole head should be shaved. The same applies even more if associated with a depressed skull fracture.

Complications, Early and Late, From Intracranial Injury

Meningitis.—Treatment is carried out with the use of suitable antibiotics and sulfa drugs. If penicillin is chosen it can be administered in six hourly doses of 300,000 units, and some combination of antibiotic therapy should be continued until one week has passed following the return of the temperature to normal. Sulfa drugs can also be administered, giving 1 Gm. of sulfadiazine every 4 hours after an initial dose of 2 Gm. If sulfa drugs are used, it is important to examine chemically the level which is maintained in the blood stream and also to make sure that the patient is voiding properly. The result should be followed by daily lumbar punctures. In many severe cases intrathecal spinal injection of suitable antibiotics can be made. Before the introduction of penicillin and other antibiotics and of sulfa drugs, it was possible to cure some patients with streptococcal meningitis by forcing fluids and making repeated lumbar punctures every day. This type of treatment is no longer necessary. However, adequate fluid intake and lumbar punctures to check progress are essential.

Osteomyelitis.—For osteomyelitis of the skull, x-ray examination is important along with the question of tenderness and edema. The treatment is block removal of the osteomyelitic area supported by suitable antibiotics or chemotherapy.

Brain Abscess.—The treatment of brain abscess is discussed in the following section. In the final analysis it is a question of evacuation of the abscess, its proper drainage or its complete removal. If it has been removed completely and cleanly, it is possible to obtain primary closure.

It is extremely important to prevent the production of a brain abscess by adequate débridement of the original scalp laceration.

Post-Traumatic Headache.—Post traumatic headache is part of a so-called post concussional syndrome and may be due to too long or too short a period of bed rest. It may be due to a slight residual collection of fluid, increase of pressure, or disturbance of proper cerebrospinal fluid circulation which could have been relieved by lumbar puncture or could be

Fig. 126—A, Extensive electric burn which has destroyed the scalp and caused necrosis of the skull seen in the picture. The dura beneath the bone was found to have completely disappeared.

B, Preliminary burr hole opening made through the necrotic skull, and escape of large quantity of extra-arachnoidal pus.

C, Fascial graft to replace dura now covered with healthy red granulations about 12 days after removal of necrotic skull.

D, Residual skull defect.

F, A pedicle flap was transferred from the abdomen to the defect in the scalp, using wrist as a carrier (Baxter).

on a psychologic basis if the patient feels that there is something more which should have been done. It can often be relieved by lumbar puncture or encephalogram. It is possible, in rare instances, for a subdural clot or effusion to be overlooked, and, in an occasional case, even brain tumor. The headache may be focal in type or generalized. In some instances it follows lumbar puncture and is then due to a low intracranial pressure from a cerebrospinal fluid leak through the opening in the spinal dura.

Post-Traumatic Dizziness.—This is generally described as an unsteady feeling which the patient states is within his own head. He notices it especially on head movement, e.g., on getting up in the morning. It is common especially when patients have not been well treated, referring especially to the minor closed head injuries. Sometimes it is associated with depressed fractures which may be associated with adhesions. Psychologic adjustment in the form of simple explanation and discussion with the patient, exercise, and work generally suffice to cure. If more radical measures are necessary encephalography may be advisable, which has the advantage of eliminating the possibility of a subdural hematoma and also causes sufficient shift in the pressure relationships that symptoms may disappear. It should be used with psychologic reinforcement. When the dizziness due to a head injury is more vertiginous in character so that objects appear to move and to turn before the eyes of the patient, it is then probably due to a fracture involving the labyrinth. This condition clears up spontaneously in time.

Facial Paralysis.—If the 7th nerve has been paralyzed and fails to show any evidence of recovery, it indicates involvement by pressure of bony fragments within the facial canal. In some selected cases, when spontaneous recovery of function does not occur, an exploratory decompression of the nerve by the otologist is advisable and has given good results.

Post-Traumatic Epilepsy.—To avoid post-traumatic epilepsy, meticulous débridement should be performed at the original operation. Further than this there is little that helps. When epilepsy has developed it is a question then for evaluation and for trial on anti-

convulsive therapy, and the question of surgery may eventually be considered. For a discussion concerning the incidence of post-traumatic epilepsy, see Brock.

BRAIN ABSCESS

MacEwen of Glasgow obtained remarkable results by simple drainage of brain abscess. Nevertheless, since his time, results have been variable and frequently unsatisfactory for certain types of abscess. The care and skill of the surgeon has much to do with the prognosis. Much time and labor are now spared and success more likely to be assured with the antibiotics. Metastatic brain abscesses have generally had a high mortality in the past. Further, the type of organism has affected the results. Modern treatment with the use of antibiotics has considerably reduced the mortality rate.

Abscesses may be divided as follows:

- 1 Single
- 2 Multiple
- 3 Metastatic
- 4 Post-traumatic
5. Phlegmonous

Etiology

Single abscesses most commonly arise in civilian life from mastoiditis or from frontal and ethmoidal sinusitis. From the mastoid, the abscess is generally located in the temporal lobe or the adjacent cerebellar hemisphere. From the frontoethmoidal sinuses, it is generally found in the frontal lobe.

Multiple abscesses may occur in one lobe or in scattered areas of the brain. Two abscesses have not been uncommon, one in the frontal and one in the temporal lobe, presumably from sinus infection.

Metastatic brain abscesses, which may be single or multiple, disseminate most frequently from the lungs in cases of bronchiectasis. A so-called paradoxical abscess occurs as a result of septic emboli from a peripheral area passing via a patent foramen ovale to the brain.

Post-traumatic abscess, as the name implies is found beneath or in association with a traumatic wound of the scalp, cranium, or both.

Phlegmonous designates a cluster of small abscesses bound with much interstitial inflammatory tissue. This state occasionally occurs in any of the above groups.

In the case of abscess from sinus infection, the process may be by direct extension through involvement of the successive coverings of the brain and spread via the Virchow-Robin spaces. This process includes focal osteomyelitis and focal pachymeningitis and leptomeningitis. Spread may occur by retrograde venous thrombophlebitis by way of veins passing from the infected mastoid antrum, tympanic cavity, or involved sinus.

The infection in the metastatic type is carried by the arterial blood current as a septic embolus from a distant focus, such as a pulmonary or renal abscess. Septic emboli lodge generally in the middle cerebral distribution. Forty-five per cent of the metastatic type are solitary.

In the case of trauma, cerebral abscess formation is generally by direct extension. It may follow a simple blow but usually complicates a penetrating wound. It may come from the fracture of the base involving a sinus, or an area of softening may serve as a locus minoris resistentiae in which bacteria may lodge. The reaction of brain to infection is similar to that of other tissues. There occurs an intense mesoblastic reaction, with exudation of leukocytes, proliferation of endothelial granulation tissue, production of macrophages from microglia and from mesothelial elements, and formation of a connective tissue capsule. The final result is a pus-filled cavity surrounded by a variably formed connective tissue capsule. The surrounding glial elements undergo hypertrophy and hyperplasia. A brain abscess from within out shows formation of a typical structure in concentric layers, with a pus-filled core surrounded by radially disposed granulation tissue and macrophages, a connective tissue capsule, and with the whole surrounded by a variable thickness of reacting glial tissue.

Diagnosis

The general symptoms and signs are those usually seen in cases of increased intracranial pressure which may or may not be associated with headache. Focal signs may be present or absent. Convulsions may occur. A careful his-

tory will generally reveal otitis media, mastoiditis or sinusitis, a furuncle, an infected tooth, infected wound, or bronchiectasis.

The story is often confusing and clinical diagnosis difficult as the following case summaries will show.

A patient who was admitted in decerebrate rigidity had suffered with his right ear since an attack of measles at the age of 11 years, and had undergone two operations on his right ear (mastoid) before admission. He had had a head cold a few days before, with pain in the right ear, headache, drowsiness, and unconsciousness on the day of admission, with bilateral plantar extension, twitching of the left arm and leg, and attacks of decerebrate rigidity and weakness of the left foot. The optic discs were hazy.

A patient who was found to have two abscesses suffered from a draining ear, drowsiness, and aphasia.

Another patient developed sudden headache, vomiting, dizziness, chills, prostration, normal pulse rate, stupor, coma, and aphasia. Temperature 102°-103° F, hemiparesis, hemianopia. Diagnosis, metastatic brain abscess, probably arterial spread.

Major events taken from a more typical history can be listed briefly thus: pneumonia 4 months before admission, three seizures in 3 weeks, headache 3½ weeks, drowsiness 3 weeks, papilledema, and weakness of left arm recent.

Another history from a case of trauma follows: scalp laceration while tobogganing, repaired, infection, depressed fracture discovered, osteomyelitis, brain abscess drained with cure, result satisfactory but with very occasional convulsions.

The above will give sufficient idea of the variable course of the symptoms and signs in brain abscess.

Diagnosis is difficult. Accurate history of essential points and general physical and neurologic examinations should make one suspect the possibility of brain abscess in most cases and in many, localization can also be given.

For final diagnosis ventriculography may be used, but with an accurate clinical conclusion some would prefer to omit this. The author prefers the precision of diagnosis by ventriculography. This last is dangerous and so must be done carefully, as release of pressure places extra strain on the capsule of the abscess which may rupture. Encephalography by the spinal route might be done in very simple cases but is very dangerous on account of the possibility of cerebral herniation at the incisura tentorii or the foramen magnum.

Lumbar puncture is highly dangerous, and the leak which persists, as also the immediate drop of pressure, may cause rupture of the abscess or a cerebral herniation. The main use is to measure intracranial pressure, which, however, often gives a false reading. If checked by slight jugular compression, this adds to the risk. The principal excuse for lumbar puncture concerns the cell count in the cerebrospinal fluid, as many cases of brain abscess are associated with meningitis. The presence of both meningitis and abscess makes diagnosis very difficult. Enough has been said to show that lumbar puncture is always a hazard. It is prudent, therefore, that this be done when necessary by the man who is ready to operate.

Treatment

Treatment varies from time to time, and in the hands of different surgeons. The basic principle is evacuation and drainage. There are many methods, all of which must be carried out by a trained surgeon, and the postoperative treatment must be carefully supervised, otherwise re-collections are likely to occur.

Various methods of surgical treatment which have been described may be briefly listed as follows:

1. Drainage with suitable large plastic or rubber tube

2. Aspiration of contents and insertion of suitable antibiotic on one or more occasions may suffice and, if necessary, subsequent drainage or surgical exposure, marsupialization, or removal

3. Decompression by craniotomy with subsequent removal of the abscess as it wanders toward the brain surface and its wall thickens

4. Marsupialization of the abscess so that the abscess will eventually turn itself inside out at the surface of the brain

5. Tube and balloon drainage

6. Packing of the exposed cavity in an acute case with moist gauze

7. Simple removal without rupture in a well-encapsulated case

Simple tube drainage, though perhaps more crude than other methods, is in any event a good standard method for all types of cases, and the mortality rate is very low.

Of all the methods of treatment which include the above, the author believes that simple tube drainage is the safest method in the long run and gives consistently good results. In all cases the well-formed capsule and its contents can frequently be removed without rupture.

FIG. 127.—A, Extreme ventricular displacement from case of metastatic left parietal brain abscess.
B, Drainage by tube method.

case of metastatic abscess of the temporal lobe simulating tumor was removed in this way in toto as is customary, by the author for tumor. This proved on section to be a typhoid abscess.

containing motile bacilli. The patient had had typhoid fever several months before the abscess was found.

Treatment by the tube drainage method has to include rigid supervision of the postoperative dressings and control of intracranial pressure. It is important to bring the pressure low at dressings by lumbar puncture as pointed out by Cone, so as to open up the cavity. The author prefers to keep the pressure below and to normal in the first two days. After the period of swelling is over, pressure is allowed to rise from normal to slightly above, in order to collapse the cavity more quickly. Before the era of antibiotics, the drainage tube from a cerebral abscess cavity could be removed in 12 days. Today with antibiotics it is removed in 3-5 days.

The mortality with the help of chemotherapy is now low, if all precautions are taken. It was low before chemotherapy, but wounds had to be more carefully supervised. The only feared complication is late epilepsy which develops in approximately one third of the cases.

INTRACRANIAL TUMORS

Intracranial tumors may be divided into the following main groups (after Cushing):

- 1 Gliomas and ganglioneuromas
- 2 Meningiomas
- 3 Perineurial fibroblastomas
- 4 Pituitary tumors
- 5 Congenital tumors
- 6 Blood vessel tumors
- 7 Papillomas
8. Sarcomas
9. Metastatic tumors
- 10 Granulomas
11. Cysts

The history and the general symptoms and signs, both focal and general, produced by the majority of the above lesions seem to become more and more characteristic for any particular tumor as one gains experience. Much can be deduced, however, from the few observations made under the preceding sections.

The symptoms and signs of disease of the central nervous system must be elucidated in terms of anatomy and physiology.

The biologic behavior of the various types of tumor is exceedingly varied.

Gliomas

The gliomas form 44% of all brain tumors in patients coming to a neurosurgical clinic. They arise, as the name indicates, from the neuroglia, which form the normal supportive tissue of the central nervous system. Nevertheless they are ectodermal elements. The term does not include the microglia which are thought to be, and behave physiologically as, mesodermal derivatives.

To understand the classification of the gliomas, it is necessary to review the histologic development of the normal glial cell which is illustrated in Fig. 128.

Bailey and Cushing (1926) formulated the first satisfactory classification of the gliomas, basing it upon their histogenesis. Minor changes have been introduced but, in the main, their classification is satisfactory. As any one tumor may contain cells which are multiplying at different levels of development, one may classify a tumor according to the most primitive type of cell that is seen in any number. This is more logical, as many different tumors may show a preponderance of one type of cell.

The relative incidence in a series of 210 gliomas of the central nervous system from the Montreal Neurological Institute is shown in Table 11.

Ependymoma	13.33
Spongioblastoma polare	5.23
Oligodendroglioma	3.80
Oligodendroblastoma	
Pinealoma	.95
Neuroepithelioma*	.47
Case of astrocytoma and glioblastoma multiforme (case of triple tumor)	.47
Unclassified	9.52

*Includes two neuroepitheliomas of the peripheral nervous system.

Astrocytomas may occur at any level of the central nervous system and at almost any age. The greatest incidence is in the second, third, fourth, and fifth decades, with the average for the cerebral hemisphere 33.2 years, for the cerebellar hemisphere 34.2 years, for midline

cerebellar cases 9.5 years, and for the spinal cord 43 years.

They are slow in growth. Preoperative symptoms average 30 months but may go on for years. Similarly the postoperative survival may be years and there may be no recurrence.

This large group has been subclassified (of some practical importance) into at least three types

1. Piloid
2. Gemistocytic
3. Diffusum

Into the piloid group are placed all the tumors in which the dominant cell is a fiber-

forming astrocyte. It is true that there are some which are forming few fibers

It is found that this tumor is the one which frequently forms cysts (in 3 out of 10 cerebral cases and 11 of 14 located in the cerebellum). The piloid astrocytoma may occur in the cerebrum, cerebellum, and spinal cord and is rather evenly distributed over six decades. It has the longest prognosis. A 20-year or longer postoperative survival may be hoped for with adequate removal. Every effort should be made at total ablation. The average age for this group when in the cerebrum is 34 years

The gemistocytic type is composed of plump swollen astrocytes with a large amount

Fig 128—Development of glia (After Penfield, 1931.)

Fig 129—Cystic astrocytoma showing mural nodule and ventricular shift

Fig 130—Gemistocytic astrocytoma showing invasion of gray and white matter and widening of convolutions.

of cytoplasm but few rather large, short processes and a minimum of fibers. This tumor occurs almost wholly in the cerebral hemisphere. The average age incidence is 39, and the majority occur in the fourth and fifth decades of life. There may be a long preoperative and postoperative history, but generally less than for the piloid group. The tumor is likely to be rather fast growing. A 10-year survival is uncommon. Large cysts are uncommon but medium-sized intraneoplastic cysts occur in about one third of the cases.

Fig 131—Astrocytoma diffusum Shows diffuse invasion of cerebral hemisphere

The astrocytoma diffusum is so named because of its penetrating characteristics. It is formed of small stellate astrocytes which may be called protoplasmic astrocytes. They tend to wander through the gray matter, passing ganglion cells without destroying them. Sometimes groups form into more solid areas, but these may not be large. Cells pass considerable distances beneath the pia. In the depth of the white matter they may infiltrate and here tend to form fibers. The average age incidence in the above series was 34.5 years, but the majority occur toward the fifth decade in the late thirties. The preoperative symptomatology is shorter, on the average, but many cases go

years before recognition, generally with epilepsy. Because of its infiltrating character, it is difficult to find and recognize and to delimit it at operation. A 10-year postoperative survival is not uncommon.

The surface of the brain may look somewhat whiter than normal, but convolutions are often well preserved. X-rays show merely a uniform shift. Post-mortem examination shows a general slight enlargement of the whole hemisphere. This tumor does not form cysts of any gross size and it occurs in the cerebrum. Unlike the protoplasmic astrocytoma of Bailey, it has not been found in the cerebellum. Some of these tumors can be removed *en bloc*, but sometimes it is wiser to leave them and use x-ray therapy.

The next large group of gliomas is the glioblastoma multiforme. This is a most malignant type generally found in the cerebrum, with an age incidence of 41.2 years and generally occurring in the fourth, fifth, and sixth decades. The preoperative history is, on the average, about six months and frequently less. The postoperative history is short unless a very radical removal is made, in which case one occasionally obtains a longer survival.

The cell type is probably the small polar spongioblast, but the tumor is generally composed of a variety of cells representing different stages of development. Malignant necrosis is common and endothelial budding of vessels and mitoses are frequent. Cysts may occur within the growth but are medium in size and likely to contain thick necrotic material.

There are different ways of dealing with these neoplasms. One is biopsy verification and let alone, especially if speech centers are involved. Another is radical removal. The author believes that radical removal is justified with lobectomy. One such patient has now survived six years. All procedures may be followed with x-ray therapy if desired.

The third large group is the medulloblastoma group, first so classified by Bailey and Cushing (1923). These are primarily tumors of children in the first two decades, though curiously the average age is 19 years, as a few are seen in adults. They occur exclusively in the cerebellum, generally coming from the midline structure, the vermis, or the lateral recess of the 4th ventricle. They are highly malig-

nant and eventually seed out into the cerebrospinal fluid and sometimes metastasize by way of cerebrospinal fluid down the spinal cord and over the brain. They have a short preoperative history, on the average 6 months, and the postoperative survival varies from a few months to several years. Radical removal followed by x-ray therapy is generally recommended. In many cases of removal, recurrence has been delayed for 2-5 years, and in rare cases patients have been known to survive for many years. The tumor is very sensitive to x-ray, and equally satisfactory results are reported by some where the patient is treated with x-ray therapy alone.

one was reported to arise from the 4th ventricle (Cushing). It has been known to arise from a peripheral nerve. Relatively good results have occasionally been obtained in cerebral cases, especially in children.

One rarely encounters tumors in which the type cell belongs to the neuroblastic development. The ganglioglioma may arise at any level of the nervous system, in the cerebral hemisphere, and in the cerebellum. It is to be expected in association with the spinal ganglia as a paravertebral tumor. It is relatively benign and, if completely removed, is not likely to recur. Neuroblastoma is composed of more

Fig 132—A, Arteriogram shows elevation of middle cerebral arteries by glioblastoma multiforme containing abnormal vascular network.
B, Arteriogram of the opposite normal side for comparison.

The remaining gliomas cannot be considered in detail here. They are less frequent. Some are relatively benign. They all have their own special biologic characteristics.

The astroblastoma is somewhat more malignant than the astrocytoma. Ependymoma is moderately benign and arises in proximity to a ventricle or the neural canal. This is also typical for spongioblastoma polare. Oligodendroglioma is generally found in the cerebrum. It is rather malignant, with an average age incidence of 40 years. Pinealoma is found generally in younger individuals. It may be associated with *pubertas praecox*.

Neuroepithelioma is highly malignant and occurs occasionally in the cerebral hemisphere;

immature type cells and has been found in the cerebral hemisphere and midbrain.

Meningioma

The meningiomas form the next major group of brain tumors (13.4% in the series of Cushing, 14% in the series of Montreal Neurological Institute). As the name implies, they take origin from the meninges, and though generally attached to the dura, it is thought that they arise from meningeal cell rests. For example, the author has frequently noted their attachment at the site of a pachionian body. Different varieties have been described by Cushing but common is the meningeal fibroblastoma. The type cell is the

meningeal cell which is mesodermal and may form fibroglial fibers, reticulin, and collagen

These tumors grow to huge size before giving rise to symptoms. They merely displace brain but at their point of attachment invade dura locally and even the cranium, thickening it and passing through it. One can then see an elevation of the scalp. X-ray may reveal an area of bony thickening or endostosis and an increase in size and number of vascular channels. They arise typically at various points along the midsagittal line adjacent to the falx cerebri. They do occur along the line of the fissure of Sylvius. They commonly arise from various regions at the base, lesser wing of the sphenoid bone, dorsum sellae, tuberculum sellae, olfactory groove, floor of the middle fossa, petrous ridge, posterior fossa, foramen magnum, spinal dura, and meninges.

If removed in toto, including involved skull and dura if necessary, they do not recur. Sometimes they show sarcomatous tendencies, in which case they may recur unless radically removed. An osteolytic lesion of the bone may signal such a lesion. They are technically difficult to remove due to general increase of vascularity of the whole region, and it may be necessary to interfere with the great blood sinuses. Arteriography may be of assistance to the surgeon in revealing the pattern of the blood supply.

Perineurial Fibroblastomas

The perineurial fibroblastomas form another group (8.7% in the series of Cushing, 5% in the series of Montreal Neurological Institute). They are benign tumors which arise from perineurium and are found attached to cranial or spinal nerve roots and less often to a peripheral nerve. They do not recur when removed completely. A common type is the acoustic neuroma that occurs so frequently in connection with the 8th nerve as to derive its name from that characteristic. As the tumor enlarges in the cerebellopontine angle of the posterior fossa, it compresses the anterolateral aspect of the pons and the cerebellar hemisphere. Paralysis of the 8th nerve occurs very early, followed by the 7th nerve. The 5th cranial nerve is often involved and less frequently the 9th, 10th, and 11th nerves. The

symptoms and signs can be worked out on the basis of the anatomic structures affected.

Acoustic neuromas characteristically arise from the intracranial portion of the nerve at and within the entrance to the porus acusticus, which is usually seen to be enlarged in x-rays. Acoustic neuromas can be removed completely, in which case they will not recur. The removal generally presupposes section of the facial nerve which leaves the patient with a disfiguring abnormality. This can be largely overcome by suitable nerve transplantation. The most satisfactory method is to join the proximal end of the 12th nerve to the distal end of the 7th, and the proximal end of the ansa hypoglossi to the distal end of the 12th cranial nerve.

The next great group are the metastatic tumors (6.6% in the series of Montreal Neurological Institute). These are generally found by the neurosurgeon in the cerebral hemisphere but may occur at any level. The usual source is from the lung.

A solitary secondary tumor of the hemisphere should be removed for relief of headache, the results are often remarkably good. The patient may recover completely for an indefinite period.

Pituitary Tumors

The pituitary adenomas (6.9% in the series of Montreal Neurological Institute) may be divided into the chromophil or acidophilic, the chromophobic, and the basophil or basophilic, which give characteristic syndromes. They all produce certain symptoms in common. Increase of intrasellar pressure causes headache which is usually bitemporal. When the adenoma escapes from the confines of the sella turcica there is relief from headache until the local pressure rises again or until there is an elevation in the general intracranial pressure. When the tumor is sufficiently large, pressure upon the optic chiasm results, first in an upper quadrant bitemporal or bitemporal hemianopia. Various degrees and combinations of field defect can occasionally occur, leading eventually to blindness in one or both eyes, according to the pattern of impingement upon the chiasm and the optic nerves.

Chromophil adenomas are composed mainly of acidophilic or eosinophilic cells containing alpha granules. This type of tumor en-

larges the sella turcica as it grows. It causes disturbances of growth hormones, which lead to gigantism and acromegaly.

Chromophobe adenomas are the most common type. The cells resemble the chromophobe cells of the pituitary. These contain few, if any, acidophil particles. They grow to a large size and soon rupture through the confines of

the sella turcica. They tend to produce symptoms of hypopituitarism.

Basophil adenomas are formed by a growth of the basophilic cells of the pituitary which contain specially staining beta granules. These tumors are generally very small and can be seen on cross section of the pituitary gland. They are associated, however, with very grave

Fig 133—A, Ventriculogram shows tremendous ventricular shift.
 B, Depression of lateral ventricle and large vascular channels within the skull

 D, Vascular blush still visible in subsequent plate.

symptoms known as basophilism, characterized by polycythemia, hypertension, adiposity with pendulous abdomen and striae, hypertrichosis, amenorrhea.

Adenocarcinoma of the pituitary is a rare growth; biopsy and attempted removal are made.

When adenomas of the pituitary grow large enough to cause signs of compression of the optic nerves, operation is indicated. Before this, x-ray therapy can be employed if the indications are evident. The acidophilic tumors are generally considered to be the most radiosensitive and can be held in check to a considerable degree by roentgentherapy. Hormonal therapy has to be instituted as necessary.

failure of temperature regulation, somnolence, and disturbances of vision. They are slow in growth. Removal is very difficult and frequently one has to be satisfied with mere emptying of a cyst or with partial removal. Hypophysectomy in the treatment of cancer of the breast is described in Chapter 14.

Miscellaneous Tumors

Other rare congenital tumors of the brain are cholesteatomas, dermoids, teratomas, and lipomas. They occur in fairly characteristic locations and can generally be removed completely or at least partially.

Blood vessel tumors (4% of cases) include hemangioblastomas and hemangiomas. The

Fig. 134—A, Large arteriovenous angiomatous formation fed by main branches of the middle cerebral artery.

B, X-ray taken approximately 4 seconds later.

Epitheliomas of the hypophyseal duct arise from cell rests along the tract of the primitive craniopharyngeal duct or hypophyseal duct. They are composed primarily of epithelial cells in various types of formation with cystic spaces large or small which contain cholesterol crystals. There is usually a deposition of calcium, and the growths are often seen by x-ray. The symptoms are caused primarily from a disturbance of pituitary function and pressure upon the optic chiasm and hypothalamus. These consist of disturbances of growth and nutrition and metabolism, hypophyseal cachexia or Simmonds' disease, dwarfism, sexual infantilism, adiposogenital dystrophy, diabetes insipidus,

former are in gross appearance not unlike a glioma but on section are found to be formed of angioblastic or reticulo-endothelial elements. They are frequently associated with cyst and usually are located in the cerebellum. They are benign and if removed completely do not recur. Hemangiomas are difficult to differentiate from congenital anomalies of blood vessels and are probably such. The basic lesion is generally an arteriovenous connection. Cerebral arteriography is of paramount importance in the diagnosis of these lesions. Many of these formations can be removed with good results. They are prone to cause convulsions, headache, and sometimes hemorrhage.

Papillomas occur rarely from the choroid plexus and can be removed if producing symptoms. They occur in about 0.5% of cases.

Sarcoma of the dura is not common. Meningiomas sometimes take on sarcomatous tendencies.

Perithelial sarcoma of the brain (0.7% of cases) is not uncommon and usually occurs in the cerebral hemisphere. The treatment is removal and roentgentherapy.

Melanotic sarcoma may arise from melanoblasts in the leptomeninges.

Tuberculomas can be successfully removed if they produce symptoms. In some countries they are common.

Syphilomas rarely occur in this country and are prevented now by chemotherapy.

Echinococci cysts are common in some countries, they are treated surgically

THE VERTEBRAL COLUMN AND THE SPINAL CORD

The Vertebral Column

The vertebral column consists of 33 segments: 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 or 5 coccygeal. Both sacral and coccygeal segments have become fused into single bony masses known as the sacrum and coccyx, respectively. The movable vertebrae are separated by the fibrocartilaginous discs. They consist of a body and a laminal arch supported by two pedicles. The apex of the laminal arch protrudes as a spinous process.

The transverse processes jut laterally as extensions of the laminal arch and pedicle. There is a superior and an inferior articular facet on either side of a vertebra which affords a certain amount of movement; this varies for each and every vertebra. The vertebrae lie in series one above the other, their flattened superior and inferior surfaces separated by discs of fibrocartilage which allow some movement and also afford a resilient cushioning effect. The thoracic vertebrae, in addition, possess one or two facets for the head of the corresponding rib.

The vertebral bodies are held together by the strong annulus fibrosus of each disc and by the anterior and posterior spinal ligaments. Further, the vertebral spines are joined by strong interspinous and supraspinous ligaments.

The laminal arches are bound together by the elastic ligamenta flava.

When viewed from the side, the vertebral column exhibits a double S-shaped curve which is convex forward in the cervical and again in the lumbar regions and is concave forward in the dorsal and in the sacral regions.

The cervical vertebrae are the smallest and most movable. The upper two, the atlas and the axis, have a very special articular connection with the base of the skull and with each other, which permits the necessary movements of rotation in the transverse and the antero-posterior directions. Between the atlas and the axis, besides the arthrodial diarthrosis between the vertebral arches on each side, there is a special rotatory diarthrosis between the dens of the axis and the articular facet on the posterior surface of the anterior arch of the atlas. Several special ligaments bind the vertebrae together.

As the cervical vertebrae possess the greatest mobility, dislocation most readily occurs in this region. In the dorsal region there is greater rigidity, as it is supported by the thoracic cage. In the lumbar region there is moderate movement, and a common level for fracture is at the dorsolumbar junction.

The vertebral canal lies beneath the laminal arches and the intervening ligamentum subflavum. The floor is formed by the posterior spinal ligament which lies upon the posterior aspect of the vertebral bodies and the annular capsule of the intervertebral discs. The canal is narrowest in the dorsal region.

Related to each pedicle is a canal through which passes the corresponding nerve root. One root, the first, passes between the skull and the atlas. This means that the 1st cervical root passes from the vertebral canal above the first vertebra. Seven cervical vertebrae are described, but there are 8 pairs of cervical nerves, so that the 8th passes out below the 7th vertebra and the 1st thoracic nerve passes below the 1st thoracic vertebra, and all nerves below this level make their exit below the vertebra from which they are named.

The Spinal Cord

The cord is enclosed by three membranes. The inner consists of the pia mater spinalis, which is said to be somewhat thicker than the

which covers the brain but the function and anatomic relationships are similar. It carries within it the blood vessels for the spinal medulla. The arachnoid is a delicate membrane continuous with that covering the brain, and between it and the pia mater is the subarachnoid space. The inner layer of the cranial dura extends down to form the outer tough covering of the spinal cord.

Fig. 135—Relative position of spinal nerve segments to vertebrae

As the nerve roots leave the vertebral canal, they carry a covering of these membranes which fuses with the connective tissue sheaths of the peripheral nerves on leaving the intervertebral foramina. Between each pair of nerve roots there is the dentate ligament which arises from the pia mater along the lateral side of the spinal cord. Below each root a sickle-shaped slip of this ligament passes laterally to form a pointed attachment to the dura. This occurs between each pair of nerves down to include the 1st lumbar.

The blood supply to the spinal medulla comes from the anterior and posterior spinal arteries and from spinal branches passing through the intervertebral foramina from the vertebral arteries and from the intercostal and the lumbar arteries. The venous drainage is by way of six longitudinal channels which form a plexus in the pia mater. This empties into the internal vertebral venous network which, in turn, empties into the vertebral, intercostal, and lumbar veins and into the cranial venous sinuses and plexus above.

Until the third month of fetal life the spinal portion of the medullary tube runs the full length of the vertebral canal. From there on, however, a discrepancy in rate of growth occurs, so that at birth the end of the spinal cord only reaches as far as the 1st lumbar vertebra. Because of this, nerve roots within the vertebral canal take a progressively increasing downward inclination. The lumbosacral nerves tail off below the conus of the spinal cord in what is known as the cauda equina. Puncture of the spinal subarachnoid space may be safely performed in the lumbar region below the level of the spinal cord.

In considering spinal localization, the relative position of the nerve segments and the spinal roots in relation to the vertebral column is of greatest importance. Thus the 5th lumbar nerve segment in the spinal cord lies at the level of the body of the 12th dorsal vertebra, but the nerve root runs all the way down to pass out of the vertebral canal between the 5th lumbar and the 1st sacral vertebra. A smaller discrepancy will occur as one comes to each succeeding higher level. The 1st lumbar nerve segment probably lies at the level of the body of the 10th dorsal vertebra; the 8th dorsal over the 6th dorsal vertebra, the 1st dorsal over the 7th cervical; the 4th cervical beneath the 3rd cervical, and so on. It must also be remembered that the vertebral spines in the dorsal region overlap considerably.

The paired nerve roots leave the spinal cord at regular intervals. Each pair of nerves which includes sensory and motor nerves, in addition to autonomic fibers in certain regions, supplies a certain area of skin and muscle. Such a region of supply is known as a spinal dermatome or nerve segment. The segmental innervation

of muscles is recorded in standard textbooks of anatomy.

The cutaneous areas supplied by each nerve segment have been mapped in considerable detail in man by Head and by Foerster; in the monkey by Sherrington, who employed the method of "remaining sensibility" in which three consecutive nerve roots above and three below a single intact root are sectioned. The area supplied by the remaining root can then be outlined and is the maximal for the intact root. The segmental dermatomal distribution in

for the appreciation of hot and cold sensations which are conducted in separate though closely packed laminae. Light touch is thought to pass largely by way of the contralateral ventral spinothalamic tract. Certain grades of touch also pass by the posterior columns

Musculotendinous sensory impulses, as tested by joint position, two-point discrimination, appreciation of weight, figure writing, vibration sense, and such discriminatory functions, pass via the posterior columns of Gall and Burdach, or the *fasciculi gracilis* and *cuneatus*.

Fig 136—Segmental dermatomal distribution

man was studied in considerable detail by Head in patients with herpetic eruptions. Foerster recorded the areas of vasodilation after antidromal stimulation of the posterior roots and also mapped the dermatomal distribution by the method of remaining sensibility in clinical cases

At this point, one may merely mention that conduction of painful sensory impulses passes up the spinal cord by way of the contralateral lateral spinothalamic tracts. This is true also

The autonomic pathways are not well known. The lateral corticospinal tract, subserving motor impulses, lies in the lateral funiculus immediately posterior to the rubrospinal tract. Impulses to the cerebellum from muscle, tendon, and joints pass by way of the dorsal and ventral spinocerebellar tracts

Anatomic Localization

In spinal surgery it is of first importance to know the exact level at which the lesion is

situated, which is determined by neurologic examination.

The sensory level below which there is loss or reduction of sensation to painful stimuli may be determined. The sensation for hot and cold should be tested when more detailed examination is required; and in certain spinal lesions, a dissociation of involvement may be found. Similar testing of musculotendinous sensation must be made to determine the level of loss of function.

Autonomic disturbance may be judged by palpating the skin of the patient. The skin may be dry below the level of involvement because of the absence of sweating in the denervated areas, whereas above, it may feel moist. The presence of sweating may be demonstrated by placing the patient in a warm chamber and painting the skin with a preparation of iodine, and dusting starch powder over this. A blue coloration will occur in the presence of moisture. Other tests have been devised, and a very satisfactory method is relative measurement of skin resistance with the dermograph.

Motor power must be tested and relative weakness and paralysis listed, not forgetting the trunk musculature, for example, the intercostal muscles and the rectus abdominis. Spasticity, flaccidity, and atrophy have to be adjudged. In addition, the tendon reflexes, both deep and superficial, are examined. Thus, with proper examination, one may determine the level of the lesion by evaluating

- 1 Sensory levels
 - (a) pain, heat, cold, light touch
 - (b) muscle, tendon, joint sensation, i.e., position sense, two-point discrimination, figure writing, vibration sense
- 2 Motor levels
 - (a) muscle power
 - (b) muscle atrophy
 - (c) muscle tonus
- 3 Coordination by suitable tests
4. Autonomic levels
 - (a) palpation of sweating level
 - (b) sweating tests, chemical
 - (c) dermograph
- 5 Reflex level
 - (a) deep reflexes
 - (b) superficial reflexes

It must be remembered that damage to the spinal cord will cause a transitory abolition of deep reflexes below the level of the lesion. The plantar reflexes may vary according to the completeness of damage. This period is known as the period of spinal shock. In the lower animals it may last but a few hours or days but in man persists for several weeks. It is said to remain longer if infection or cachexia is present.

It may be mentioned here that if the spinal cord were hemisectioned, the motor paralysis by virtue of the crossed pyramidal fibers would be ipsilateral, as would be the loss of discriminatory sensation, but the loss to the modalities of pain, heat, and cold would be on the opposite side due to the crossing of the fibers below the lesion. This hypothetical type of neurologic manifestation is called the *Brown-Séquard syndrome*. It is not usual to have such a sharply defined lesion clinically, but frequently modifications of it are seen.

In addition to the above, which may give a fairly accurate level, there are some special signs which are of great importance and afford a regional localization.

- 1 Horner's syndrome
- 2 Paralysis of the diaphragm
- 3 Disturbance of bladder function and weakness of the anal sphincter

Horner's syndrome is dependent upon interruption of the autonomic sympathetic pathway at any point from the hypothalamus to the muscle controlling the pupil of the eye. The autonomic fibers pass out via the 8th cervical root and upward by way of the cervical sympathetic chain. The syndrome consists of miosis, enophthalmos, and slight ptosis. It is most common to encounter this sign in tumors at the level of C8.

It must be remembered that the diaphragm derives its main central nerve supply from the phrenic nerves, which emerge from or with the 3rd, 4th, and 5th cervical roots. It may also be mentioned here that the function of the intercostal muscles can be tested on simple palpation, and a motor level can be demonstrated, if present, in this way. The abdominal muscles can be palpated during the contraction. The umbilicus will move upward if muscle segments below it are weakened, i.e., Beever's sign.

The bladder is supplied by sympathetic fibers from lumbar roots 1, 2, 3, (4) and by parasympathetic fibers from roots S 2, 3, 4. The parasympathetic fibers cause contraction voluntary control is possible. Various effects upon bladder function are produced by injury to the spinal cord. This includes a phase of shock resembling spinal shock on the somatic

Fig. 137—Brown-Séquard syndrome

of the detrusor muscle and the pudendal nerve relaxes the external sphincter. Cerebral autonomic fibers pass upward and downward in the spinal cord, but these tracts are not as yet well known. Normally a certain amount of side in which bladder tonus may at first be lost and subsequently increased to produce a hyperactive bladder of small capacity and of frequent emptying. At this juncture, it may be well to mention that ideally bladder function

in the paraplegic patient can best be treated in the initial stages, at least, by tidal drainage, which is an automatic syphonage system that rhythmically empties the bladder. After a period of treatment, it is felt that the bladder capacity will be greater than without this automatic device. In wartime it may be necessary to resort to suprapubic cystostomy.

A block below the thoracic level is likely to show reduction of respiratory oscillations, but fluctuations occur on pressure over the abdomen or on straining. A block at the lumbar level will show none.

In addition to the level of the lesion one may judge as to whether the lesion is intramedullary, intradural, or extradural, both by

Fig 138—Pathways responsible for normal micturition. Diagram shows sympathetic, parasympathetic, and somatic nerve supplies of the bladder. Note that the parasympathetic fibers carry the impulses which are responsible for contraction of the detrusor muscle and that the pudendal nerve relaxes the external sphincter. The role of the sympathetic system in the act of micturition is somewhat indefinite.

Lumbar Puncture.—Localization of the lesion may be made very accurately by neurologic examination, which can be checked by lumbar puncture studies and by myelography. One may in fact determine by spinal manometric test not only whether a subarachnoid block is present but also to some extent the level at which it exists. Thus on jugular compression a block in the cervical, thoracic, or lumbar region will show an absence of response in the manometer below the block. A

block below the thoracic level is likely to show reduction of respiratory oscillations, but fluctuations occur on pressure over the abdomen or on straining. A block at the lumbar level will show none. In addition to the level of the lesion one may judge as to whether the lesion is intramedullary, intradural, or extradural, both by the history and by the neurologic examination.

An intramedullary lesion is generally painless, but an extradural and especially an extradural one will cause pain first. There will be more gradation of sensory loss and dissociation of modality in respect of pain, temperature, and touch sensation in the intramedullary type.

The vertebral canal can be considered to be divided to some extent by the dentate ligament into anterior and posterior compartments. Some

idea as to whether it lies anteriorly or posteriorly in the intervertebral canal can be adjudged by the neurologic examination. Thus a spinal lesion should be described as having its upper level at such and such a spinal nerve segment, and its lower level, which is more difficult to determine, estimated.

Lumbar puncture manometric study will give evidence of absolute or relative block. This will aid in the differential diagnosis regarding presence of an expanding lesion, adhesions, etc. Due to the realization that Pantopaque can be easily withdrawn at the end of the procedure, this test is generally combined or supplanted by myelography. The site of blockage can then be seen under the fluoroscope and upon x-ray films.

as spina bifida anterior. When a similar occurrence occurs in the skull, it is known as cranium bifidum. Experimental work, however, produced evidence to the effect that defects occur when an embryo is subjected to abnormal environmental conditions. It is believed that they might occur from faulty implantation as a result of endometritis in pregnancy.

These bony anomalies are generally associated with failure of the meninx to differentiate into its three characteristic layers. Logically and grossly it retains an embryonic type of structure, and in some cases the meningeal-like tissue is thick and spongy. The pressure of the cerebrospinal fluid then causes the meninges to bulge through the skeletal

Fig. 139 Spina bifida myelocoele showing probable attachment of cauda equina beneath center of thin dermal covering.

Spina Bifida and Cranium Bifidum

Lesions Arising on the Basis of a Malformation.—The neural tube closes toward the end of the third week of intrauterine life in the human fetus. Mesoblastic tissue growing between the covering ectoderm and the separated neural tube forms the membranous and bony coverings of the entire nervous system. By the 11th week the vertebral canal is covered, roofed by the neural arches from the 1st cervical to the 3rd or 4th sacral vertebral level. Occasionally there is failure in the process of closure of the laminae, which results in an anomaly called spina bifida. Rarely this occurs anteriorly through the body of the vertebra, usually the sacrum, in which case it is known

in the form of a fluid-filled sac known as a meningocele. Often nerve roots and frequently spinal cord may be drawn into the sac, in which case it is called a myelomeningocele. Various degrees of developmental failure of the nervous elements are seen in these cases. In the case of herniation of brain tissue in association with cranium bifidum the anomaly is called an encephalomeningocele or encephalocele. In severe spinal defects there is frequently and primarily maldevelopment of the myeloid element. The neural tube itself may have failed to close in which case there may be an associated failure of the meninges and vertebral coverings to close. Usually the laminae are widely open and the verte-

pedicles are considerably separated. The meninges are thin and the skin like transparent parchment. One can see the undeveloped neural element or primitive spinal cord running sagittally as a double band along the inner side of the transparent covering. This represents the most complete type of defect, spina bifida with myelocoele, and is generally not suitable for surgery. It is sometimes called rachischisis completa.

Fig 140—Case of spina bifida occulta showing subcutaneous pad of fat and scar tissue dissected free, revealing stalk which enters vertebral canal

Fig 141—Cranium bifidum with meningocele

In the other extreme, very simple defects may occur through the laminal arch and in rare cases are hardly more than a notching of the laminal arch. In these there is generally a thin stalk which runs out from the level of the dura

into the subcutaneous tissues. The end of this is often enveloped in a ball of fatty and fibrous tissue which bulges beneath normal-appearing skin. This type is called spina bifida occulta.

Between these extreme examples are the meningocele and the myelomeningocele described above.

In rare cases there is an epithelial tract that runs from the skin surface to and into the dural sac and is continuous with an intraspinal epidermoid or dermoid cyst. This condition is recognizable as a button of thickened, discolored skin, usually in the midlumbar region, with a small, central dimple which marks the external opening of the dermal tract. The area may be surrounded by a light growth of hair. These lesions occasionally occur in the skull, usually involving the posterior fossae.

Spina bifida occurs occasionally in more than one member of a family and occasionally in successive generations. A family history was admitted in 65% of cases by Ingraham, et al. Occasionally more than one meningocele presents in the same patient.

Surgical cases of spina bifida and cranium bifidum may be classified as follows:

- 1 Spina bifida occulta
- 2 Spina bifida with meningocele
- 3 Spina bifida with myelomeningocele or myelocoele
- 4 Spina bifida with syringomyelomeningocele
- 5 Cranium bifidum with meningocele, encephalocele, or meningoencephalocele
- 6 Spina bifida associated with epithelial sinus and dermoid

Symptoms and Signs

In the case of *spina bifida occulta* there may be no neurologic defect. On the other hand, there may be weakness and wasting of the muscles of one leg and sensory loss and disturbance of bladder function. The signs probably arise as a result of traction on the spinal roots or spinal cord as a result of anchorage by the filum terminale or nervous and fibrous attachments. There is, of course, no emergency about operating upon this type, and patients may not be referred for treatment until adolescence, when complications have become more

Actual muscle weakness may be present as can be demonstrated by asking the patient to pull or push against resistance while testing dorsiflexion and plantar flexion of the foot and of the toes. A useful test is to ask the patient to stand on his heels and on his toes; this will reveal weakness of the flexor muscles on the one hand and of the extensor muscles on the other. The ankle jerk is generally hypoaffective or absent in an L5 to S1 herniation, but less likely to be lost in an L4 to L5 protrusion. The knee jerk is usually reduced in an L3 to L4 rupture. One may see fibrillation or fasciculation in some of the involved muscles.

The Lasègue sign is generally positive when there is clinical evidence of disc disease in the lower lumbar region. When the thigh is flexed at the hip, pain occurs when the leg is extended on the thigh, supposedly due to stretching of the sciatic nerve or a part thereof which causes radiation of pain. In some cases there occurs only pain in the lower back and hip. On the contrary, flexion of the hip alone without extension at the knee, will not cause pain. This is helpful in making a differentiation between a spinal lesion such as a ruptured disc and a lesion about the hip joints. The sign can be intensified by dorsiflexion of the foot. In exceptional cases when the test is negative, the Lasègue sign can be modified by the raising of both legs together. This practically always gives a positive result. Tenderness over the lower lumbar spine in the gluteal region, posterior thigh, calf, and the Achilles tendon can usually be elicited.

A useful test is to allow the patient to lie on his back with legs hanging over the end of the table or side of the bed. This generally causes increase of pain which can be relieved by raising one or other or both legs to the horizontal. Deviation of the legs to the right and to the left may also then accentuate the pain.

In the standing position it will generally become obvious that the patient has some degree of scoliosis, tilting of the pelvis, lumbar muscular spasm, and/or reduced lordosis and may be unable to straighten up. The patient protects the leg on the affected side by flexing the knee. In acute conditions this is sometimes quite extreme. Bending forward may increase

the scoliosis and muscular spasm, with limitation of movement which will be obvious and frequently causes linking and locking. Certain movements produce low back pain with some degree of sciatic radiation. Bending backward and to the left and to the right will generally cause some of the above subjective and objective phenomena.

Fig. 142.—A, Myelogram shows almost complete block at the level of L1-5 interspace.

B, Shows marked spurring at the 3rd, 4th, and 5th interspaces.

C, Myelographic defect shows protrusion at level L1-5 on the right.

D, Myelogram shows protrusion at L1-S1 on right and evidence of bilateral protrusions at the L1-5 level.

Radiologic Examination.—Simple x-rays at the required level may show narrowing of the disc shape with some osteophytic reaction. Increase of protein is often found in the cerebrospinal fluid. Roentgenologic examination with the aid of radiopaque substances is desirable when possible. An air or an oxygen myelogram had for a time some popularity but has been superseded by Lipiodol, which can be aspirated

from the spine following the study, and more recently by Pantopaque, which is thinner and can be aspirated more easily. Up to 9 ml. of Pantopaque is injected, and the needle remains in situ during fluoroscopy and the taking of films. At the completion of these studies the material is removed by aspiration. The material should be run as high as the thoracic region and can be carried on to the cervical if indicated.

Diagnosis.—Clinical examination and the myelogram should be in agreement, and when this is the case, operation can be considered. When they do not coincide, the question of

as well as the more uncommon granulomas. It is not necessary to prolong the list of other possibilities.

Treatment.—Treatment resolves itself into nonoperative and operative. In *nonoperative* treatment bed rest alone can effect marked improvement. Plaster jacket for some six weeks, possibly in a position of slight flexion, or in any event in a comfortable position, may cause a temporary cure. It is, however, probably not much better than simple bed rest. Application of heat, massage, and exercises may be of value. If conservative measures fail, operative treatment may be indicated.

Fig. 143—A, Myelogram shows defect at the C6-7 level on the right side, suggesting large herniation of the intervertebral disc.

B, X-ray shows narrowing of the intervertebral space and slight spurring at the C6-7 level.

operation has to be left to the experience of the individual surgeon. In differential diagnosis one has to consider spondylolisthesis which, of course, can be diagnosed with the x-ray and sometimes even on palpation. It may also be associated with a disc herniation. Tumor of the cauda equina, metastatic lesions, and chordoma of the vertebral column may confuse the picture. A tumor of the sciatic nerve is a rare possibility. Tuberculosis must be considered,

The question as to whether the disc should be removed and whether simultaneous fusion should be carried out has been a source of discussion between neurosurgeons and orthopedists. In the author's opinion spinal fusion is not necessary as long as the disc has been radically removed. It is possible that some degree of soft tissue fusion will take place if the disc is radically removed, and it has been shown by Cone and Rabinovitch that when the

disc is completely removed, including the cartilaginous plate in animals, actual bone fusion takes place. Because of the amount of separation between the human vertebral bodies, bony fusion, in the author's opinion, is not likely to occur. It is necessary to remove sufficient bone from the laminal edges for good exposure and especially from the posterior aspect of at least the entrance to the nerve root canal in order to decompress the nerve root satisfactorily. It is important to explore adequately for the disc as on some occasions it may point more medially or more laterally and in rare instances lie between the nerve root and the dura further caudal than one would expect, and occasionally it migrates a short distance up or down the vertebral canal.

In carefully selected cases the results are satisfactory in at least 80% of patients. In some the leg pain disappears while they may be left for a period of time with a feeling of weakness, stiffness, or occasional backache. This, no doubt, may be due to mechanical factors but, frequently, merely to muscular spasm. It can usually be cured by suitable exercises. In the case of lumbar discectomy the author allows the patient bathroom privileges on the day following operation but otherwise prefers to keep the patient in bed for 8-12 days.

Cervical Discs

Diagnosis.—The herniated *cervical disc* presents a special problem. The signs and symptoms are similar, except for the location, to those found in the lower lumbar region, giving rise to attacks of neck pain with radiation down the arm, sometimes with numbness and a feeling of paresthesia and of weakness with atrophy. The most common site for the hypaesthesia is over the radial distribution, generally root C6 or C7, coming from a disc at the level of C5 to C6 and C6 to C7, respectively. Tilting the head passively to one side and jerking it slightly will frequently elicit pain in the side of the neck which may or may not radiate. There is often a point of tenderness over the transverse process of C6. X-rays of the cervical spine show a narrowing of the disc with some spurring of the bone. The normal cervical curvature is altered, and limitation of movement can be seen by po-

sitional x-rays. The diagnosis is further confirmed by myelography.

Treatment.—The results in cervical disc removal are very satisfactory. Operation in this area is more hazardous than in the lumbar region because of the proximity of the cervical spinal cord. For this reason conservative treatment should be given a very adequate trial before operative interference is considered. A collar of felt or plaster can be worn to support the chin. Bed rest for a short while and linear extension by halter traction can also be tried. It is highly important that the nerve root be adequately decompressed in the procedure of cervical discectomy, which should be undertaken only by an expert in the surgery of the central nervous system. The results in this type of operation are highly satisfactory.

Thoracic Discs

Herniations at other levels are generally non-surgical and may fail to be recognized, as they do not cause pain due to the relative position of the root in respect to the disc. However, on some occasions, they do, in which case symptoms and signs will correspond to the level involved. In the *thoracic region* they may cause compression of the spinal cord with resulting degrees of paralysis and loss of bladder function. When such is the case and when the localization is exact, operative removal is indicated. The level again can be checked by myelography. However, one must guard against artefacts of myelography, especially in the thoracic region. Operation in the thoracic region is particularly difficult. Some cases of cervical and thoracic disc disease have simulated multiple sclerosis.

Fracture-Dislocation of the Spine With Neurologic Involvement

The general plan of procedure has been to send the patient as rapidly as possible by ambulance or airplane to a hospital that is sufficiently well equipped and is best suited for dealing with these cases. This is true both in military and in civilian practice.

The diagnosis must be suspected at the time and at the site of the accident by rapid examination of the patient. The history, the clinical signs of pain or tenderness, spasm, paresthesia, anesthesia, and paralysis should deter-

mine the diagnosis. If the patient is unconscious one has to rely upon the immediate history of witnesses and the objective signs. Palpation of the cervical spine may reveal loss of proper alignment, ecchymosis and swelling may be present over the dorsolumbar spine.

During transportation, if conscious, the patient must remain flat on his back for cervical fracture and his head must be braced or held between sandbags or kept in linear extension. For lumbodorsal fracture, lying prone on a stretcher may be desirable, preserving normal dorsolumbar curves, or supine on a firmer surface if the patient is conscious. Much will depend upon the state of respiration, as naturally a good airway is essential. The unconscious patient is transported more safely lying prone.

On arrival at hospital, neurologic examination, ecchymosis, swelling, sensory level, paralysis, etc. should at once give an idea of the site of the fracturing. These will give an indication of the most important areas to be x-rayed. Distention of the bladder must be controlled by catheterization. Further treatment will depend on the type of fracturing, the neurologic signs, and the presence or absence of complicating factors such as multiple injuries, etc.

If cervical fracture-dislocation has occurred, one must consider the following surgical procedures:

Gradual reduction of the dislocation by linear traction of the spine. This can be carried out by one of three methods:

1. Halter or chin strap traction
2. Skull traction by chrome steel wire passed through burr holes or trephine holes
3. Skull traction with tongs
 - a. Crutchfield
 - b. Barton-Cone

The first method is not satisfactory. It is painful and cannot be sustained long. The second is unnecessarily complicated but is a good method. The third is simple and is satisfactory and comfortable. With these last two methods the patient can be properly nursed and turned safely, and an operation can be performed while the patient is in traction.

After reduction by the skull traction one must decide whether an open operation is de-

sirable. It is preferable to explore and fuse in any case where complete dislocation has occurred or where multiple fractures have occurred, usually of the body and of the laminal arches. Such an operation is made while the traction apparatus is in place. The operation consists of (a) *exploration* and (b) *reduction*, which is often complete when the surgical wound is exposed. One may if necessary open the dura mater a short distance to view the condition of the cord and the vertebral canal for encroachment by bone or fibrocartilage. The dura is then repaired. One can elevate any bone which presses in from the laminal arch

Fig. 144—Skull traction by linear extension, using the Cone Barton ice tongs.

When the wound is satisfactory, an internal fixation is made by a fusion operation, usually using parallel grafts of bone from the tibia or the ribs. *Os purum* has also been tried and homologous bone from the bone bank is now commonly used. After the stitches are removed, a suitable plaster cast can be applied and the patient allowed up.

Similar procedures are carried out for dorsolumbar fractures, but here linear skeletal traction is difficult. In simple cases of fracturing of the body without neurologic signs, the usual

reduction by hyperextension can be used, but when the fracture is more complicated, includes the pedicles and arch, and especially if neurologic signs are present, this maneuver is dangerous as it may cause a narrowing of the vertebral canal. In these cases, open operation, exploration, decompression, repair of dura, and replacement of roots of cauda equina, when necessary, should be carried out. This may be

done with shoulder and foot traction apparatus applied during the operation and with some degree of hyperextension to correct the bony deformity. Cone has developed special apparatus for this purpose. In addition, a spinal fusion is employed to hasten recovery by strengthening the spine. The operative method of treatment is preferable in most of these cases, but if this is not easily possible, the

Fig. 145—*A*, X-rays demonstrate fracture-dislocations at the level C1-2.
B, Spinal fusion after reduction by skeletal traction of fracture-dislocation at the level C1-2.

absolute indications for operation might include a condition in which a narrowing of the vertebral canal has occurred, such as by a depression or displacement of a portion of the laminal arch or body, which has caused a degree of paralysis. Satisfactory x-rays are important in making this decision. This can be

checked by lumbar puncture and a Queckenstedt test to determine whether a spinal block is present. The absolute indications to justify operation for such cases cannot be properly defined in so short a space as too many variables are possible, and procedure will depend on the findings in each particular case.

Fig 146—*A*, Severe fracture-dislocation of the first lumbar and adjacent vertebrae.
B, Spinal fusion with parallel tibial bone grafts after exploration and decompression under skeletal traction.

Of greatest importance is the attention to the urinary bladder. This should not be allowed to become distended. Initial catheterizations should be done at suitable times, followed as soon as possible after operation by the establishment of an automatic bladder. It may require many weeks before this can be established. In the meantime, tidal drainage is employed, but if this is not possible (as it requires considerable care on the part of the surgeon) one must rely upon catheterization and, if necessary, suprapubic cystostomy. After a certain time it should be possible to stop continuous catheterization and employ manual pressure every 2-3 hours, at regular intervals catheterizing for the residual. In this way the patient may develop a reflex emptying bladder. If it is not at first successful, this can be tried again after another week or so.

For the various grades of paraplegia the problem of late convalescence and rehabilitation has become more hopeful in the last few years due to the research of Munro, the School for the Crippled and Disabled in New York, and of various Centers for paraplegia in Canada and the United States which have been developed since World War II. The patient ideally should be sent to a rehabilitation center, but this is not essential. He must learn to strengthen the muscles of the shoulder girdle so that he will eventually be able to use crutches and perhaps learn to walk in splints. He can learn a gainful occupation, learn to drive an automobile, have a wheel chair, etc., and especially to look after himself, his bladder, his bowels, and to dress himself. In the words of Helen Barton, "he must learn to live again," so that he will become self-reliant and self-supporting.

Fig. 117—The Cone operating table with traction apparatus applied

Of equal importance is the prevention of bedsores by sufficient turning and massage of the patient over the important areas. If they develop, further care is necessary. Plastic surgeons may prefer to repair with skin flaps. If this is not desirable, they can be healed by proper cleansing, débridement, and nursing care.

Spasticity may become a troublesome complaint. It may be minimized by adequate physiotherapy. More radical methods of dealing with this symptom will not be discussed

Infection of the Spine

Tuberculous infection of the spine is more properly treated as an orthopedic condition and is discussed in that section. Only when signs of paraplegia develop from pressure of tuberculous granulation tissue or pus is the neurosurgeon involved. In such cases a decompressive laminectomy and spinal fusion are indicated.

Nontuberculous and acute pyogenic involvement of the spine may occur as an osteomyelitis, in which case it may have arisen at a

complication of a surgical procedure. Exposure and packing with antibiotics are usually necessary. In the case of spontaneous infection, it has been possible to effect a cure with antibiotics alone without operation. Rare chronic infections such as blastomycosis occasionally occur.

Another form of spinal infection takes place as an epidural abscess. This condition arises spontaneously, apparently as a result of a metastatic infection lodging in the epidural tissues. This gives rise to general signs of acute infection to which are added spasticity of spinal muscles and consequently some arching of the back, together with marked tenderness and pain which may be girdlelike. Any movement causes great pain. If unrelieved, spinal compression occurs with paraplegia. The treatment is open operation, packing, and the use of antibiotics.

Tumors of the Vertebral Column

Neoplasms of the vertebral column will cause pain and eventual compression of the spinal cord. Some may be listed as follows:

A. Benign

- 1 Benign giant cell tumor
- 2 Chondroma
- 3 Osteoma
- 4 Hemangioma
- 5 Myeloma

B. Malignant

- Primary—1 Osteogenic sarcoma
 2 Lymphosarcoma
 Secondary—1 Chordoma
 2 Metastatic carcinoma

Each cannot be discussed in detail. Suffice it to say that the ideal treatment for *benign giant cell tumor* is as complete removal as possible followed by deep x-ray therapy. In the *primary tumors*, decompressive operation, biopsy, and attempted removal are desirable, followed by deep x-ray therapy.

The remaining tumors are removed so far as possible when they produce symptoms or signs.

Paget's disease is sometimes associated with sarcoma. This sometimes calls for decompression and removal. Decompression is also indicated when simple compression occurs in *Paget's disease*. X-ray treatment is very effective in some cases of sarcoma of the spine.

Secondary carcinoma of the spine becomes a neurosurgical problem when it causes pain or paraplegia. Pain can be relieved by suitable spinotthalamic tract section, paraplegia can be prevented by decompressive laminectomy, with partial removal of the neoplasm, and the segmental pain can be relieved by simultaneous extradural root section.

Tumors Arising Within the Vertebral Canal

Tumors arising within the vertebral canal may be classified in the same manner as brain tumors. They fall naturally into a group of tumors arising from the meningeal coverings of the spinal cord and the nerve roots, and another which grows from and within the spinal cord itself. It may be pointed out that there is also a group of extradural tumors that are listed above under tumors of the vertebral column. In addition to these conditions already mentioned, Hodgkin's disease should be added; the lymphogranulomatous tissue usually lies in the epidural space with some attachment to the outer layer of the dura. Surgical removal may be necessary.

Epidural tuberculous granulation tissue may be encountered and is generally treated by antibiotics and orthopedic measures.

Parasitic cysts should also be mentioned, though rare in this country.

Tumors Arising From the Meningeal Coverings.—The *meningeal fibroblastoma* is a benign tumor which arises from an attachment to the dura. This neoplasm probably originates from arachnoidal cells within the dura. It is usually reddish yellow, discrete, firm, attached to the dura, finely lobulated, and encapsulated. Meningiomas occur mostly in the dorsal region. This tumor must be removed completely with the involved dura. If this is done, there will seldom be a recurrence. This may be technically difficult. The author generally lays in a fascial graft or a split dural graft. Some leave the dura open.

Perineurial fibroblastoma arises from the epineurium and perineurium of a nerve root, usually the posterior root. These tumors are generally intradural. They are yellow, firm, discrete and benign and must be removed completely and the nerve root probably sacri-

ficed. The nerve fibers spread out over the capsule of the growth and can be dissected free. If removal is complete, there will be no recurrence.

A *neurofibroma* has the general appearance of the above though it is somewhat whiter and firmer and the nerve fibers pass into the mass rather than through its capsule. There will be no recurrence if removed completely. There may be multiple *neurofibromas* and other evidence of von Recklinghausen's disease.

results, but in the more malignant types, and if paralysis is severe, the result will only be relative. *Medulloblastoma* of the cerebellum commonly metastasizes to the spinal meninges.

Syringomyelia is sometimes associated with tumor, in which case it is preferable to call it tumor with cyst, granted the cyst may traverse a considerable distance and even the full length of the cord. Here the treatment is as for tumor. *Syringomyelia* proper occurs without tumor and is usually thought to be asso-

Fig. 148—Stages of removal in case of perineurial fibroblastoma at the level of L2. Note nerve attachment to right of retractor.

Tumors of the Spinal Cord.—Tumors of the spinal cord itself consist mainly of the gliomas. The more common are the astrocytomas and the ependymomas and occasionally glioblastoma multiforme and spongioblastoma polare. These tumors call for exploration. They can be removed with very satisfactory

results. In some cases exploration and incision of the cyst are indicated to relieve signs of pressure and possibly pain. *Syringomyelia* is associated in some cases with a congenital anomaly at the craniospinal junction in which the odontoid process is tilted backward and impinges on the anterior surface

of the spinal cord and medulla. Decompressive operations have been performed for this condition. In some the condition is confused with a dilated neural canal which is known as a hydromyelia of the spinal cord.

Other Rare Conditions.—Other rare conditions include *lipoma* of the cord, which is generally irremovable without causing much disturbance of function. *Spinal dermoids* are difficult to remove, but with careful dissection complete removal is often possible and prognosis may be good.

Improvement results if the area of adhesion is small and delicate, arachnoiditis circumscripta, but often this process is extensive, and it is difficult to obtain regression of signs even with meticulous dissection.

PERIPHERAL NERVES

The nerve supply of the upper extremity is derived from the anterior rami of the 5th, 6th, 7th and 8th cervical and the 1st dorsal nerve roots. In the so-called pre-fixed plexus there is a contribution from the 4th cervical

Fig. 149.—Peripheral nerve sensory skin areas

Tuberculomas of the spinal cord rarely come to operation.

Angiomas of the spinal cord may be encountered.

Subarachnoid parasitic cysts should also be mentioned though rare in this country.

Adhesive arachnoiditis is a rather uncommon condition in which a dense layer of adhesions is discovered involving the pia arachnoid membrane. Sometimes postoperative im-

provement results if the area of adhesion is small and delicate, arachnoiditis circumscripta, but often this process is extensive, and it is difficult to obtain regression of signs even with meticulous dissection.

The anterior spinal nerve roots are composed of the axonal processes of nerve cells situated in the anterior columns of the gray

matter of the spinal cord from which they emerge as rootlets from the region of the anterolateral sulcus. The posterior spinal roots are formed by the proximal axonal processes of cells in the ganglia of the posterior spinal root which lie at the level of the intervertebral foramina. The anterior and the posterior roots pierce the dura separately. Thence they share a common sheath which includes the spinal ganglion of the posterior root. The distal processes of the posterior root ganglia and of the anterior roots continue to share a common sheath and become, by definition, spinal nerves as they leave the intervertebral foramina.

Due to regrouping in the various nerve plexuses the distribution of the peripheral nerve fields will necessarily differ from that of the sensory root dermatomes. An approximation to the general representation is given in Fig. 150.

Posterior Cervical Plexus

The posterior cervical plexus as distinct from the cervical plexus is constituted by communicating branches from the posterior rami of the 1st, 2nd, and the 3rd, and possibly 4th cervical nerves. The greater occipital nerve

Fig 150—Brachial plexus

On leaving the intervertebral foramina the spinal nerves divide into primary posterior and anterior branches. The posterior rami innervate the skin of the head and trunk posteriorly and the longitudinal muscles of the spinal axis. The anterior branches supply the whole lateral and anterior parts of the body, including the limbs, and form the great plexuses. The spinal nerves each are joined by at least one gray ramus from the paravertebral sympathetic ganglionic chain. Each anterior root, from the 1st dorsal to the 2nd and 3rd lumbar segments, supplies one white ramus communicans to the sympathetic chain with efferent fibers.

arising from the posterior ramus of the 2nd cervical nerve supplies sensory fibers for the posteromedial half of the occipital scalp. The 3rd occipital nerve supplies the skin more laterally and comes from the 3rd posterior ramus. The 1st cervical nerve does not generally contain sensory fibers, and motor branches are of little surgical importance.

The occipital nerves are sometimes injected with Novocain or alcohol in cases of occipital neuralgia. Seldom is this necessary. Generally these cases are psychologic. The greater occipital nerve can be injected most readily 1" lateral to the greater occipital protuberance at the

level of the superior nuchal line. It can be localized more accurately by faradic stimulation.

Cervical Plexus

The cervical plexus is formed by the anterior rami of the upper four cervical nerves. The sensory fibers pass by way of the lesser occipital nerves (C2, 3), great auricular nerve, nervus cutaneus colli, and descending supraclavicular branches (C3, 4) to supply the skin of the lateral third of the occipital scalp, the side of the neck, and the area of skin overlying the angle of the mandible bounded above by the distribution of the trigeminal nerve. The peripheral nerve fields and the dermatomes which they supply are of importance, principally in diagnosis. Thus, in a cervical fracture dislocation at the C2, C3 level one may find an anesthesia in the area supplied by the lesser occipital and the greater auricular nerves.

From a surgical point of view the most important motor branch arising in part from the level of the cervical plexus is the *phrenic nerve* which contains fibers from the 3rd, 4th, and 5th anterior rami of the cervical spinal nerves. Passing obliquely across the scalenus anticus muscle the nerve must be identified and isolated in the operation for scalenotomy. Phrenicotomy with avulsion of the phrenic nerve has been used in the treatment of tuberculosis in order to collapse the lung by immobilizing the diaphragm. Regeneration seems to take place in a few months. Paravertebral growths or direct trauma may affect the phrenic nerve, and examination should include both observation and fluoroscopic examination of the diaphragm.

Brachial Plexus

The brachial plexus is formed from the anterior rami of the 5th, 6th, 7th, 8th cervical and the 1st dorsal nerves. In some cases the 4th cervical nerve contributes a branch and in other instances the 2nd dorsal sends a branch.

The nerves undergo a reassortment as they pass downward and laterally in the posterior triangle of the neck toward the first rib over which they pass into the axilla. Three primary cords are formed. The *upper cord* is formed by union of the 5th and 6th nerves. The *middle cord* is represented by the 7th alone

and the *lower cord* by the 8th cervical and 1st dorsal nerves. At the same time the nerves divide into anterior and posterior trunks. Regrouping results in the formation of three secondary cords. The *lateral cord* is formed from the anterior trunk of the 5th, 6th, and 7th nerves, a *medial cord* from the anterior trunk of the 8th cervical and the 1st dorsal (part), and a *posterior cord*, to which all of the posterior trunks from the 5th to the 1st dorsal, inclusive, belong.

The secondary cords pass over the first rib in the subclavian groove surrounding the superior, posterior, and inferior aspects of the subclavian artery between the scalenus anticus and the scalenus medius muscles.

Anatomic localization is important in the case of lesions in the neighborhood of the brachial plexus and is made possible by a knowledge of the special anatomy of the region.

Supraclavicular lesions with nervous involvement at and proximal to the level of the primary cords are likely to involve certain nerves to muscles of the shoulder girdle and trunk and may be looked upon as supraclavicular.

Supraclavicular branches may be listed as follows (Cunningham):

Anterior branches:

- 1 Nerves to scalenus anterior and longus colli
- *2 Communicating nerve to join the phrenic nerve
- †3 Subclavian nerve

Posterior branches

- 1 Nerves to scalenus medius and scalenus posterior
- *2 Dorsal scapular nerve
- *3 Long thoracic nerve
- †4 Suprascapular nerve

A lesion of the brachial plexus at a lower point will allow the above branches to escape. A lesion further distal toward the secondary cords will develop the aspect of a multiple peripheral nerve lesion. The *lateral anterior* and the *medial anterior* thoracic nerves, the *subscapular* nerves, and the *thoracodorsal* nerve arise from the secondary cords and may be involved.

*From anterior rami of the plexus

†Level of formation of secondary cords

The following branches arise from the infraclavicular portion of the brachial plexus (Cunningham):

Anterior branches from the lateral cord:

1. Lateral anterior thoracic
2. Median (lateral head)
3. Musculocutaneous

Anterior branches from the medial cord:

1. Medial anterior thoracic
2. Median (medial head)
3. Ulnar
4. Medial cutaneous nerve of forearm
5. Medial cutaneous nerve of arm

Posterior branches from the posterior cord:

1. Axillary nerve
2. Radial nerve
3. Two subscapular nerves
4. Thoracodorsal nerve

Lesions below the level of the secondary cords will have the characteristic distribution of peripheral nerves to the arm and forearm.

Surgical Lesions.—These may be divided anatomically into those affecting:

1. Spinal roots and primary cords and branches adjacent to the vertebral column
2. The supraclavicular portion at the point of maximal mingling in the posterior triangle of the neck
3. The infraclavicular portion at the level of the secondary cords and branches

Diagnosis and anatomic localization must be made by examination of the particular muscles involved and sensory loss and sympathetic nervous involvement.

Lesions may be traumatic, neoplastic, inflammatory, and trophic.

Lesions of the three primary cords or trunks may be divided into three types:

1. The upper cervical or the Duchenne-Erb type
2. The middle type
3. The lower or the Duchenne-Aran type

The *upper radicular* or *Duchenne-Erb* type results from a lesion of the anterior rami of the 5th and 6th cervical roots or the upper primary cord to the brachial plexus. If the damage is close to the vertebral foramina, the dorsal scapular nerve, the long thoracic nerve and branches to the scalene muscles, and the

longus colli may be affected. If the lesion occurs farther distal, these branches are spared, whereas the suprascapular nerve and the subclavian nerve may be involved, together with the subscapular nerves and the lateral anterior thoracic nerves. Peripheral nerves to the arm involved may include the axillary and part of the radial fibers from the lateral head of the median and the musculocutaneous.

Muscles in the arm and forearm which derive their total or main supply from cervical nerve roots C5 and C6 are the biceps, brachialis, brachioradialis, pronator teres, flexor carpi radialis, palmaris longus, supinator. According to level of section there may be, in addition, paralysis of the rhomboidei, levator scapulae, and serratus magnus. There may be palsy of the supraspinatus, infraspinatus, teres minor, and deltoid.

The resulting deformity consists of adduction of the arm, internal rotation, extension at elbow and pronation. Conversely the patient cannot flex the arm at the elbow, supinate the forearm, externally rotate or abduct the arm. The characteristic deformity and atrophy will be diagnostic. The arm hangs with the palm of the hand rotated backward.

A lesion of the *middle primary cord*, which is composed of the 7th cervical nerve, causes principally extensor paralysis of the upper extremity in addition to paralysis of certain muscles about the shoulder and trunk. The deformity in the forearm is similar to that of a radial nerve lesion except that the brachioradialis may escape. Muscles involved are latissimus dorsi, subscapularis, teres major, triceps (part), the muscles supplied by the radial nerve, and, in addition, the nerve to the coracobrachialis. The type of deformity and treatment are similar to those for the musculospiral nerve (Stookey).

The *lower radicular palsy* (*Duchenne-Aran*) occurs with damage to the 8th cervical and 1st thoracic nerves. This gives rise to a paralysis of muscles supplied by the ulnar nerve and the medial head of the median nerve. Muscles involved are flexor carpi ulnaris, flexor digitorum profundus, flexor digitorum sublimis, flexor pollicis longus, and the intrinsic muscles of the hand. Abductor pollicis and opponens pollicis may escape since they may receive fibers from C5, C6 roots (Stookey).

The result is atrophy of the muscles along the ulnar side of the forearm and marked wasting of the small muscles of the hand. Paralysis of adduction and weakness of flexion at the wrist occur with paralysis of flexion, adduction and abduction of the fingers, extension of the distal two phalanges, opponens action, and abduction of the fifth digit. There will be a cutaneous sensory loss for C8 and D1. In addition, a Horner's syndrome may result from implication of the sympathetic ramus.

Fig 151.—Case of lower radicular palsy from traction injury. Complete paralysis of the muscles of the hand and loss of sensation along the medial side of the limb. Horner's syndrome was present.

In trauma various combinations of the above syndromes may occur. A certain lesion, however, may simulate an upper, middle, or a lower cervical lesion, a supraclavicular or infraclavicular syndrome. In the adult civilian, involvement of the upper roots is most common in injuries which forcefully separate neck from shoulder, as of a weight falling upon the shoulder, thus stretching and tearing the upper roots and nerves forming the plexus. It occurs commonly from birth injury.

The lower roots are less frequently involved but may be injured at birth if the arm is delivered in a vertical position or in an adult who catches an object with his hand to break

a fall. In injuries that cause stretching, nerve fibers may be torn from a distance, even from the spinal cord itself. Thus satisfactory suturing may be impossible. In wartime, injuries from missiles are common. Such may include severance, contusion, and concussion of the nerves.

Radial Nerve.—The radial nerve derives its fibers from the posterior divisions of C5, 6, 7, 8, and D1. Injury to the radial nerve in the arm causes paralysis of brachioradialis, triceps, extensors of wrist, fingers, and thumb. Thus paralysis is associated with wristdrop and loss of extension at the elbow and at the metacarpophalangeal joints of the thumb and fingers. This deformity should be corrected with cock-up splints. In addition, a characteristic sensory loss will be observed.

It may be injured in the axilla by fractures and dislocations of the humerus, by the pressure of a crutch, or by abnormal compression during sleep. It is frequently damaged in fracture of the shaft of the humerus and in gunshot wounds and other direct injuries.

Median Nerve.—The median nerve takes its origin from the 5th, 6th, 7th, and 8th cervical and the 1st dorsal roots by way of the outer and the inner heads. Muscles supplied are opponens pollicis, the outer head of the flexor pollicis brevis, abductor pollicis brevis, flexor digitorum sublimis, flexor pollicis longus, flexor carpi radialis, palmaris longus, pronator quadratus, pronator teres, lateral two lumbricals.

Disability results from involvement of flexion at wrist, loss of flexion of the thumb and index finger, paralysis of flexion at the proximal interphalangeal joints of all digits, loss of opponens action, and weakness of abduction of the thumb and of pronation of the forearm. Sensory loss occurs over palm and volar surface of thumb, index, middle finger and lateral half of the fourth finger and dorsal surfaces of terminal phalanx of index and middle fingers.

Ulnar Nerve.—The ulnar nerve is derived from C8, D1 by way of the inner cord of the brachial plexus. Muscles involved include flexor carpi ulnaris, inner mass of flexor digitorum profundus with the 3rd and 4th lumbricals, adductor pollicis, flexor pollicis brevis (deep part), volar and dorsal interossei, the

opponens and abductor digiti quinti. The result of paralysis is a flattened, narrow hand due to wasting of the small muscles, with the fourth, fifth, and, to some extent, the third fingers extended at the metacarpophalangeal joints and flexed at the proximal phalangeal joints, giving rise to a "clawhand" deformity. In addition, there is evidence of wasting along the ulnar side of the forearm, and the hand is in a position of radial deviation. Flexion and adduction of the wrist are weakened. Flexion at the metacarpophalangeal joints of fourth and fifth and, to some extent, of the third digit is lost. Flexion at the terminal

phalanges and extension at the phalangeal joints of these digits is also affected. Adduction and abduction of the fingers are lost. There is inability to abduct and oppose with the fifth digit and to adduct with the thumb.

Circumflex Nerve.—The circumflex nerve arises from the 5th and 6th cervical nerves. It supplies the deltoid and the teres minor muscles, the shoulder joint with sensory fibers, and the dermis over the deltoid region. It may be involved by crutch palsy and fracture-dislocation of the head of the humerus. A lesion of this nerve results in the appearance of flattening of the shoulder, due to atrophy

Fig. 152—Wrist drop from radial nerve palsy, the result of fracture of the humerus

Fig. 153—Exposure in middle third of the arm, showing extensive thickening of radial nerve, which has been freed from dense adhesions in the neighborhood of a fracture of the humerus which had been plated. Return of function occurred in a matter of weeks. Same case as seen in Fig. 152.

Fig 154—*A*, Case of typical deformity resulting from injury to the ulnar nerve immediately above the elbow

B, Atrophy of the small muscles of the hand and inability to adduct or abduct the fingers

C, Atrophy and inability to extend the 4th and 5th digits at the phalangeal joints

D, Patient fails to oppose the 5th digit to the thumb

of the deltoid muscle. The peripheral disability is due to loss of abduction of the arm.

Musculocutaneous Nerve.—The musculocutaneous nerve supplies the biceps and the brachialis muscles and transmits sensory fibers to the cutaneous areas over the radial side of the forearm and hand. The nerve to the coracobrachialis muscle is generally associated with it. Loss of flexion at the elbow is the result of involvement of this nerve. In certain positions some flexion is possible through the action of the brachioradialis. Injury may be from fracture or gunshot wound and compression.

Fig 135—Neuroma in continuity Ulnar nerve at the wrist.

Neuroma Formation

When a nerve has been left unsutured, the growing axonal processes from the central end cannot make contact with the lower segment and consequently grow into a fusiform swelling mixed with proliferating connective tissue from the nerve sheaths. This is known as a *neuroma*. Some thickening of the traumatized end of the lower segment also occurs from

mesodermal proliferation. When the nerve has not been anatomically severed one obtains a *neuroma in continuity*. The isolated processes in the peripheral segment undergo rapid degeneration, leaving the sheath of Schwann intact. When the two ends of the freshly cut nerve are brought into light apposition, the axon processes from above are directed by some chemotactic mechanism to enter the sheaths of Schwann below and down to reinnervate the part. Many fibers do not succeed in entering the degenerated nerve, but grow outside it, or enter the wrong sheaths, and lose their function.

Primary Suture of Nerves

Injury to peripheral nerves must be diagnosed through adequate history and physical findings in the light of an adequate knowledge of anatomy. In traumatic severance of a nerve,

Fig 136—Nerve suture

immediate suture should be done. The severed ends of the nerve may be cut clean with a very sharp blade and are laid close together in a normal position. Suturing should be carried out so that the upper point on the circumference of the cut central end corresponds as nearly as possible with the corresponding point on the upper pole of the distal segment. In this way the best possible approximation of the funiculi which may be seen within the cross section of the nerve may be hoped for. The severed ends are drawn together by interrupted sutures, which are passed through the nerve sheath.

It is possible to rotate the nerve, as necessary, with these sutures. Sutures are placed at equidistant points through the sheath round the circumference of the nerve. A large nerve

may require several and a small nerve two or three sutures. The two ends of the nerve sheath are drawn together so that they are in contact. The nerve fibers under these optimal conditions should barely touch.

The suture material is very fine silk or tantalum. Specially prepared sutures fused to needles are available. It is important to handle the nerve gently and as little as possible. Such manipulations as are necessary must be carried out by manipulating the sheath. In suturing, only the sheath should be held by the forceps. In early suture a satisfactory result can be expected. If the practitioner does not feel able to suture the nerve at the time of the accident, the wound may be debrided and allowed to heal and the patient sent along later for a secondary suture.

Secondary Suture of Nerve

When a nerve lesion has gone unrecognized or when exploration has been deliberately delayed in order to watch for possible spontaneous recovery, which has not materialized in a reasonable time, a secondary suture can be made. This will entail excision of the neuroma and suturing. The extent of the neuroma on the proximal end and of the scarring in the distal segment may be judged by inspection and gentle palpation. If the two ends of the severed nerve are far apart it may be difficult to bridge the gap. In this instance the distance may be shortened by flexing the neighboring joint such as the elbow or the knee joint. Following suture the joint must be maintained in flexion by plaster fixation. After 1-2 weeks the cast may be bivalved. Passive exercise can be carried on every day, and a second cast may be applied with greater extension. After three weeks it is possible for the joint to be fully extended. It is important that passive exercise be given from the start to those parts not limited by the cast, for example, to the fingers and wrist when the elbow is fixed by a cast.

A common method to effect shortening of the distance to be bridged is that of transposition of the nerve. The ulnar nerve may be transplanted anterior to the medial condyle of the humerus. The long end of the nerve is passed beneath the flexor digitorum sublimis and pronator teres muscles and then su-

tured. In making such a transplant one must consider the branches which arise at the level of transposition. In this case the branches to the flexor carpi ulnaris and to the flexor digitorum profundus may have to be sacrificed. It may be possible to bridge the gap merely by transposing the nerve anterior to the condyle and the flexor muscles. In this instance the branches to the flexor carpi ulnaris and to the flexor digitorum profundus can be spared.

Signs of returning function should be noted: return of sensation by testing light touch and pain sense, recovery of muscle tone and power by palpation, observation of the finest movements, and by disappearance of wasting. Return of function can be more precisely evaluated by the technique of electromyography when equipment is available.

Treatment of Lesions of Brachial Plexus

Traumatic lesions of the brachial plexus are difficult to treat and are likely to be discouraging in end results. Accurate diagnosis and localization are essential to satisfactory procedure. In civilian practice trauma to various parts of the brachial plexus generally occurs without open laceration. In this instance history and careful neurologic examination have to be relied upon for diagnosis. It is usual to allow a certain time to elapse to decide whether regeneration is going to occur. If obvious severance has taken place, exploration and repair should be done at once. In some instances signs of recovery may appear without necessity of exploration. Nonoperative treatment consists of affording relaxation to the nerve trunks by elevation of the shoulder girdle, with flexion at the elbow. This can be accomplished by some form of airplane splint. In simple cases a sling may be sufficient. In lower plexus lesions corrective splinting has to be devised. Suitable support and physiotherapy should be instituted to prevent muscular fixation at the shoulder.

In birth injury (Erb's) it is usual for recovery to take place over weeks and months without operation. But diagnosis must be accurate. Sufficient immobilization and relaxation to the shoulder must be maintained. This can be accomplished by securing the child's wrist to a soft cap or to the top of the bed.

Supraclavicular Compression Syndrome.—See Chapter 33, *Peripheral Vascular Diseases*.

Cervical Rib.—In order to understand this syndrome it is necessary to visualize the particular anatomic relationships that exist at the exit of the supraclavicular triangle. Looking from the side, the anterior and the middle scalenus muscles have the shape of a tent, through the door of which pass the secondary cords of the brachial plexus and the subclavian artery. The threshold is normally formed by the subclavian groove of the first rib.

Fig 157—Supraclavicular compression syndrome—cervical rib

The subclavian artery passes over the rib in the angle immediately behind the attachment of the anterior scalene muscle. Arranged about its posterior, inferior, and superior surfaces are the secondary cords of the brachial plexus. The medial cord, containing the elements of the ulnar nerve and the contribution of the medial segment to the median nerve, lies upon the first rib immediately behind the artery. Above it in order lie the posterior cord and the lateral cord. Immediately posterior to the cords of the plexus is the scalenus medius muscle. Normally there is just sufficient room for the roots and artery to pass; in fact, some muscular individuals are able to obliterate their pulse by contracting or tightening their scalene muscles.

In some individuals the muscles appear to be so well developed and so placed as to cause unusual compression at the exit of the supraclavicular triangle, thus causing symptoms and signs of nerve and of arterial compression. This was recognized by Adson as a syndrome many years after similar symptoms and signs were known to occur in the presence of cervical ribs. When a cervical rib is present the above portal of exit is even more crowded. A complete cervical rib will run all the way forward and will join the first rib just beneath or just behind the artery. It usually ends in a protruding bony hump which may lie beneath the artery and nerve or just behind them. This may exert just enough extra pressure to cause symptoms. In addition, the extra

Fig 158—Wasting of interosseous muscles. Case of cervical rib with involvement of medial secondary cord of brachial plexus

rib tends to hold the scalenus medius rigidly forward. In this way the nerves and artery are subject to unusual compression. In incompletely formed ribs there may be a continuing band to the first rib, though this must be uncommon. In other cases where only a short rib or none is visible, the tendinous band or muscular edge of the scalenus medius muscle may give pressure on the nerves.

Thus the secondary cords of the brachial plexus may be compressed in a variety of ways, each of which may produce a slightly different clinical pattern. By its musculotendinous edge the scalenus medius may play an important part in the compression syndrome to affect principally the posterior secondary cord. On the other hand, the usual ulnar involvement occurs because these fibers pass directly over

the first rib or the end of the cervical rib and are more easily damaged in the above conditions

Clinical cases may be divided into groups as follows, according to the manner in which the structures are affected

1. Patients with nerve pain
2. Patients with hypesthesia—usually ulnar, rarely radial
3. Patients with muscular wasting and weakness, usually ulnar
4. Patients with circulatory disturbances, even leading to gangrene
5. Patients with autonomic disturbances, sweating, acrocyanosis

From an anatomic point of view one might classify these cases as follows

1. Cases in which there is no cervical rib, condition presumably due to muscular hypertrophy (scalenus anticus) or the general anatomic arrangement
2. Cases due to compression by the musculotendinous border of the scalenus medius
3. Cases of cervical rib, complete, incomplete, and rudimentary with band

Treatment in clearly defined examples is generally operative. Simple section of scalenus anticus may be successful for all types. However, modifications are necessary in certain cases. The author has used the following techniques in the different types and advocates removal of the extra rib when present

1. Section of scalenus anticus
2. Section of sharp musculotendinous border of scalenus medius along with section of scalenus anticus
3. Removal of cervical rib, including the mass at its point of junction with the first rib, beneath the artery and nerve cords, with section of the scalenus anticus
4. Section of rudimentary band

Lumbosacral Plexus

The lumbar plexus is formed by the anterior branches of the first three lumbar nerves and a portion of the fourth. Occasionally there is a branch from the 12th thoracic

The 1st lumbar nerve gives rise to the iliohypogastric and the ilio-inguinal nerves. The genitofemoral arises from branches of the 1st and 2nd lumbar nerves. The lateral femoral

cutaneous nerve of the thigh arises from the 2nd and 3rd lumbar nerves. Irritation of this nerve in the inguinal region from external pressure and scarring may cause pain along the anterior surface of the thigh. This condition is called *meralgia paraesthetica*. It can be relieved by injection or resection of the nerve or by stopping the cause.

The obturator nerve is formed from the anterior portions of the 2nd, 3rd, and 4th lumbar nerves. It is sometimes injured in pregnancy. It is sometimes sectioned in order to relieve adductor spasm.

Fig. 159—Lumbar, sacral, and pudendal plexuses

The femoral nerve is formed from the posterior aspect of the 2nd, 3rd, and 4th lumbar nerves. This nerve supplies the quadriceps femoris, sartorius, pectineus, and the iliopsoas muscles.

Paralysis causes inability to flex the thigh and to extend the knee. Sensory involvement gives loss over anteromedial aspect of thigh and leg. Particular branches supply the hip and the knee joint. The femoral nerve is rarely injured but may be involved in a pathologic process, especially in the paravertebral region.

The sacral plexus arises from the anterior rami of a part of the 4th lumbar nerve, the 5th lumbar, the 1st sacral, and portions of the 2nd and 3rd sacral nerves. Branches from the sacral plexus are divided into anterior (ventral) and posterior (dorsal).

They may be listed as follows (Cunningham)

Anterior branches

1. Tibial nerve
2. Nerves to the hamstring muscles
3. Nerves to the quadratus femoris
4. Nerves to the gemelli
5. Nerves to the obturator internus
6. Articular branches (hip)

Posterior branches

1. Common peroneal nerve
2. Nerves to the short head of the biceps
3. Nerves to the piriformis muscle
4. Superior gluteal nerve
5. Inferior gluteal nerve
6. Articular branches (knee)

The *sciatic nerve* is composed of the following:

1. Nerve to the hamstring muscles
2. The tibial nerve
3. The common peroneal nerve
4. The nerve to the short head of the biceps

The *sciatic nerve* is derived from the descending branch of the 4th and of the ventral and dorsal divisions of the 5th lumbar, the 1st, 2nd, and 3rd sacral roots.

The *common peroneal* and the *tibial nerves* are the principal terminal branches. The common peroneal divides into three terminal branches:

1. Recurrent tibial
2. Deep peroneal
3. Superficial peroneal

The first supplies the proximal fibers of tibialis anticus muscle, the tibiofibular articulation, and the knee joint. The deep peroneal nerve supplies the tibialis anticus, extensor hallucis longus, extensor digitorum longus, peroneus tertius, extensor digitorum brevis; the 1st, 2nd, and 3rd interosseous muscles, articular branches to the ankle and the small joints of the foot, and the dorsal cutaneous area at the base of the great and second toes

and their adjacent surfaces. The superficial peroneal nerve supplies the peroneus longus and peroneus brevis muscles and the skin over the dorsum of the foot and a portion of the toes.

The tibial nerve supplies branches to the two heads of gastrocnemius, plantaris, soleus, popliteus, tibialis posterior, flexor digitorum longus, flexor hallucis longus, flexor digitorum brevis, flexor hallucis brevis, abductor hallucis, quadratus plantae, abductor digiti quinti, flexor digiti quinti brevis, interossei, adductor hallucis, and lumbrical muscles. Cutaneous fibers supply the plantar surface of the foot and contribute the main supply to the sural nerve for the posterolateral portion of the lower leg, heel, and lateral border of the foot, ankle, and tarsal joints. In addition, fibers from the tibial nerve supply branches to the knee joint, the tibiofibular joint, and the tarsal and metatarsal joints.

The *sciatic nerve* may be involved in neoplastic growth in the pelvis, at the sciatic notch, and along its course. Some possibilities may be listed: aneurysm at the sciatic notch, gravid uterus, sarcoma of the upper end of the femur, and trauma, as in forced manipulation for dislocation of the hip joint, contusion by fracture, open wounding, and gunshot wounds.

Complete involvement of the sciatic nerve causes paralysis of all muscles in the leg and the foot and partial paralysis of the muscles of the thigh and produces anesthesia of the foot and the lateral surface of the leg. The general practical result will include a steppage type of gait with complete footdrop. Autonomic disturbances with lack of sweating and edema of the foot also may be noted.

The common peroneal nerve is more vulnerable than the tibial. In addition to the usual forms of trauma and gunshot injuries, damage occurs as a result of pressure on the nerve, for example, in crossing the legs and pressure from casts. It results in a paralysis of dorsiflexion and eversion of the foot, extension of the toes at proximal phalangeal joints, and anesthesia of the skin of the lateral surface of the leg and dorsum of the foot.

In paralysis of the common peroneal nerve, homologue of the radial nerve in the arm, the knee is lifted and the foot swung forward

in such a manner as to clear the ground. The patient cannot dorsiflex his foot and toes from the ground.

The tibial nerve is not frequently injured except in war casualties. Trauma results in paralysis of plantar flexion of the foot and toes, of flexion and separation of the toes, and in sensory loss over the sole of the foot and the dorsal surfaces of the terminal phalanges of the toes.

In paralysis of the tibial nerve, homologue of the median and ulnar nerves in the arm, the subject cannot raise the heel from the ground or stand on the toes

The various lesions are again treated by primary suture when possible or by resection of the neuroma and suturing. Appliances to protect the paralyzed muscles from prolonged overstretching and the institution of properly supervised physiotherapy are of the greatest importance at all stages of treatment

Pudendal plexus (3rd subdivision of lumbosacral plexus) derives its fibers from anterior rami of first three sacral nerves and all of the anterior rami of the 4th and 5th sacral and coccygeal nerves. Muscles supplied by nerves from this plexus are the levator ani, coccygeus, external sphincter, transversus perinei superficialis and profundus, ischio cavernosus, bulbocavernosus, sphincter urethrae membranaceae. Cutaneous nerves supply the perianal region, perineum and genitalia, and the posterior aspect of the thigh. Autonomic fibers are dealt with elsewhere

Chapter 12

Diseases of the Face, Mouth, and Neck

Edward J Tabah, MD

Diseases of the face, mouth, and neck should ordinarily be detected early in their course and treatment instituted before serious or permanent damage has resulted. Unfortunately, this is not always the case. Infections and neoplasms in these locations are not infrequently allowed to progress to an advanced stage and may even end fatally before being recognized. Lesions in this region should be immediately apparent in most cases either to the eye or the touch or both. These two senses constitute the most valuable means of detecting abnormalities of this region, and with the aid of a few simple instruments such as laryngeal and nasopharyngeal mirrors, headlight, tongue depressors, and finger cots, the examination can be thorough and complete. Many cases of cancer are missed in their early stages simply because the examiner did not carry out a thorough and systematic examination of this region, including the base of the tongue, tonsillar region, pharynx, larynx, and nasopharynx. More important, he may neglect to carry out a careful digital palpation of the various structures in the neck and oral cavity. It is surprising how often a metastatic cancer in the neck, or a cancer in some part of the oral cavity, can be better felt than seen. Therefore each student should practice on every patient the methods of executing a thorough examination of this region until he becomes adept and develops confidence in his examination. Only then will serious lesions in this region be detected and treated at an early stage.

THE FACE

The discussion of congenital anomalies and traumatic lesions of the face, including burns and scalds, has been omitted because these are included in Chapter 10, Plastic Surgery.

INFECTIONS

The face is prone to all infections that attack the skin in general. We can divide infections of the face into two main groups: the acute and the chronic.

Acute Infections

Acute infections of the face include the following conditions: furuncles, carbuncles, cellulitis, erysipelas, and impetigo contagiosa.

A furuncle or boil is a painful circumscribed inflammation of the skin and subcutaneous tissue caused by the *Staphylococcus pyogenes*. The bacteria enter through the hair follicles or sudoriferous glands. Furuncles are particularly common on the upper lip and in the nasal region. In any serious infection of the face there may be associated edema of the face and eyelids. The main danger of a facial infection is that, if virulent, and if the patient's resistance is low, the infection may spread along the course of the facial, angular, and ophthalmic veins to produce a thrombosis of the cavernous sinus, with marked morbidity and mortality.

A carbuncle generally starts as a furuncle and may occur anywhere on the face. The

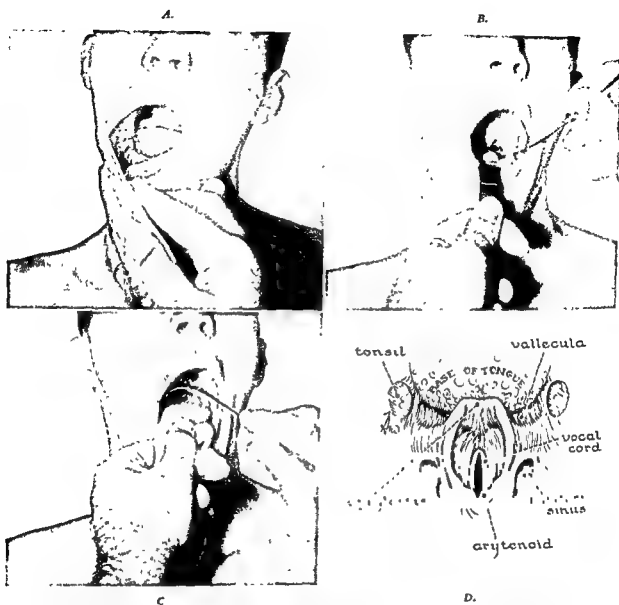

Fig 160 — Inspection of oral cavity, pharynx, and larynx

A Inspection should include a systematic examination of the lips, teeth, alveolar ridges, buccal mucosa, Stensen's duct orifice, hard and soft palates, the floor of the mouth, tongue, tonsils, pharynx, and larynx

B, Indirect nasopharyngoscopy The tongue is depressed with a retractor, and the patient is asked to breathe through both his mouth and nose. One should see the nasal septum in the midline and the middle and inferior turbinates and eustachian tube orifice on either side

C, Indirect laryngoscopy The examiner gently pulls the tongue forward, and the patient is asked to breathe through the mouth

D, Diagram showing the main structures to be visualized in the larynx and hypopharynx, as viewed in *C*

A, Bimanual palpation of the floor of the mouth and of the submaxillary and submental regions

B, Palpation of the buccal mucosa, cheek, and distal portion of Stensen's duct

C, Palpation of the anterior and lateral portions of the tongue

D, Palpation of the posterior portion or base of the tongue, the tonsillar region, and the hypopharynx

Fig 162.—Simple equipment necessary to carry out a thorough examination of the head and neck 1, headlight, 2, tongue depressor, 3, nasal speculum, 4, laryngeal mirror, 5, nasopharyngeal mirror, 6, wooden spatula, 7, rubber finger cots, 8, alcohol lamp, 9, gauze

Fig 163.—Carbuncle on forehead with secondary swelling about orbit and eyelids

causative organism is again the *Staph. pyogenes* which is of enhanced virulence, and there is an associated systemic factor, such as lowered resistance in the patient or the presence of diabetes. The lesion is characterized by an inflammation of the subcutaneous tissues and multiple areas of necrosis of the skin which rupture to produce sinuses that discharge pus. There is pain with tenderness and redness of the area and marked constitutional symptoms. Enlargement and inflammation of regional lymph nodes accompany the infection. More rarely, invasion of the blood stream may occur with septicemia and distant metastatic abscesses.

Cellulitis is an inflammation of the loose subcutaneous tissue characterized by a diffuse and spreading induration. Such a lesion may respond to therapy, with restoration of the tissues to their normal state, or the process may undergo suppuration and localize to form an abscess.

Erysipelas is an acute inflammation of the skin and occasionally of the mucous membrane, caused by a hemolytic streptococcus. According to Boyd, the site of the inflammation is the face or scalp in 90% of the cases, and the infecting organism is probably derived from the nose and nasal sinuses. It is characterized by an intense local redness and tenderness of the skin and by marked constitutional symptoms. The margins of the affected area of skin are elevated and somewhat indurated, vesicles or blebs may be present. In the more severe cases, the subcutaneous tissues are involved and suppuration may take place.

Treatment of Acute Infections—The danger of acute facial infections has been reduced since the introduction of the antibiotics. However, such infections should still be treated by the physician with great respect. In general, in dealing with these pyogenic infections, conservative measures are preferred, and surgical intervention is used only when there is definite abscess formation. At first hot moist fomentations containing a saturated solution of magnesium sulfate are applied as nearly continuously as is practical, and their application is continued until a fluctuant center develops or until the process has subsided into a subacute phase. Minor incisions to drain softened abscesses may be necessary. The concomitant use of a suitable antibiotic is essential.

Impetigo contagiosa is a troublesome pustular skin infection caused by staphylococci. It is contagious at all ages but especially so in children. The infection can run through a school or a children's ward, attacking many. It first appears as small vesicles on the face or body or about a wound. These vesicles soon become pustular, and the pustules rupture and coalesce with other sores to form crusted patches. If untreated the lesions become widespread.

In treatment, great care is taken to prevent spread of infection to other areas by protecting the sores from scratching and handling. Personal contact with others and the common use of towels must be avoided, and careful destruction of dressings is necessary. The crusts should be softened and removed by hot saline soaks, and a detergent such as pHisoderm with G-11 should be used several times daily. After removal of the crusts the involved skin should be treated by applications of bacitracin or neomycin ointment or with 3% ammoniated mercury ointment. Systemic antibiotics are usually unnecessary and, furthermore, may cause sensitization. This may deprive the patient of a valuable form of systemic treatment at a later date. In more resistant cases of impetigo that do not respond satisfactorily to local therapy, the systemic use of one of the wide-spectrum antibiotics may be necessary.

Chronic Infections

Chronic infections of the face include acne, syphilis, tuberculosis, actinomycosis, and blastomycosis and are, in comparison with acute infections, rather infrequent.

Acne generally begins at the age of puberty and is common in both sexes. The lesions are commonly found on the face but are also seen on the back and chest. It is a chronic inflammatory disease of the sebaceous glands, most frequently due to a staphylococcus. The acne may be aggravated by improper cleansing, cosmetics, or the squeezing and pressing of pimples or comedones. The inflamed glands form small red pustules which may progress to furuncles and carbuncles.

Actinomycosis and tuberculosis are fully discussed in the sections on the Neck.

Cutaneous blastomycosis is a chronic inflammatory infection of the skin characterized

by the formation of various-sized wartlike patches having papulopustular nodules. The disease is caused by a yeast organism, and the majority of cases occur in men over the age of 40 years. There is a systemic form of the disease which is generally fatal. The traditional method of treatment is a saturated solution of potassium iodide as outlined for actinomycosis. The use of stilbamidine intravenously in a dose of 150 mg daily for 12 days is promising. In resistant cases x-ray therapy is of benefit.

NEOPLASMS

Benign Tumors

Sebaceous Cysts

The most frequent sites of sebaceous cysts on the body are, respectively, the scalp, the face, and the neck, in which areas sebaceous glands are most numerous. The cysts are caused by obstruction to the duct of a sebaceous gland and therefore contain a mixture of desquamative epithelium and sebum. While the cysts may appear in any part of the face or scalp, they are particularly common behind the ears. Sebaceous cysts of the scalp are called *wens*. The cysts vary in size from 4-5 mm to 5-6 cm in diameter and are in close contact with the overlying skin. When not infected, they have a relatively tough cyst wall. As the cyst enlarges the skin is stretched, and infection may supervene to form a red, tender, and fluctuant abscess or a persistent discharging sinus. Rarely, a cyst may open to the skin surface, where the sebaceous secretion becomes dried as a *cutaneous horn*. Such cutaneous horns may develop malignant changes in the base of the cyst.

Treatment.—Sebaceous cysts should be removed for cosmetic reasons, because they may become the sites of recurring infections and because a small number develop malignant changes. Small clean cysts are best excised and closed by primary suture. When removing a sebaceous cyst, it is desirable to remove a small ellipse of attached skin with the cyst. This facilitates the dissection and lessens the danger of breaking into the cyst wall. Malignant cutaneous horns should be widely excised; if benign, more conservative excision of the horn and underlying cyst will be sufficient.

An infected sebaceous cyst should be treated by incision, drainage, and antibiotics. Complete excision is postponed until the infection has completely subsided.

Senile Keratosis

This is a degenerative disease of the skin most frequently seen on the forehead, face, or neck of elderly people. The lesion begins as a small, superficial, brownish discoloration resembling a freckle. Later it becomes raised, wartlike in appearance, and covered with a greasy scale. The scale tends to drop off, leaving a superficial, moist scab which is soon recovered by a growth of brownish scales. This lesion is definitely precancerous, and if there is a history of progressive increase in size, the lesion should be widely excised.

Dermoid Cysts

(See section on Congenital Tumors of the Neck.)

Hemangioma

(See Chapter 33, Peripheral Vascular Diseases.)

Moles or Benign Pigmented Neri

Nevus means mark or blemish and this term is often used to designate a birthmark. A so-called *mole* is a nevus which may consist of a localized pigment deposit. Moles are common about the face and neck. They may be skin colored, hairy, or show varying degrees of pigmentation. It is estimated that 90% of people possess pigmented moles. The number per person averages about 20 but may range from 2 or 3 to several hundred visible moles. While moles are benign, they are important because they can and do become malignant. It is estimated that anywhere from 30-65% of malignant melanomas arise from pre-existing benign nevi. Such melanomas are considered to be among the most malignant lesions found in man. Chronic irritation, infection, and trauma seem to play a definite role in the transformation of benign moles into malignant melanomas. It is significant that pigmented moles very rarely become malignant before the age of puberty. Such prepubertal lesions may clinically and histologically resemble a true malignant

melanoma seen in the adult. They do not, however, behave as such but rather as perfectly benign lesions.

The prophylactic removal of certain moles is completely justified, and this should be done before the age of puberty because of the increased malignant tendency after that age. Lesions to be removed are those situated in locations subject to chronic irritation by clothing or occupation, those which are darkly pigmented, and those which show any evidence of irritation or increase in size. Ackerman found the incidence of malignant change to be highest in the flat, hairless, slightly elevated, light brown mole.

The only treatment of a mole is a wide, complete excision. Nevi are radioresistant and should never be treated by methods of irradiation. The use of electrocautery or electrodesiccation as a form of treatment should be condemned because it is not generally wide or deep enough to remove all of the neval cells, and if part of the tumor remains, the irritation of this procedure has been shown to cause the cells to grow more rapidly and even to become malignant.

Malignant Tumors

Cancer of the skin is the most common form of cancer. Mortality statistics do not show this preponderance, because so many of these cases can be cured. The exposed skin surfaces of the face, ears, neck, and hands which are open to the sun's rays are the most common sites of skin cancer. Farmers and sailors who have been subject to sun and weather for years very often develop skin cancer. Persons with fair skin more frequently suffer from senile keratoses and skin cancer than those of darker complexion. Skin atrophy, skin tuberculosis, and x-ray dermatitis are precancerous conditions.

Basal Cell Carcinoma (Rodent Ulcer)

The face is the most common site of basal cell carcinoma, and basal cell carcinoma is the most common malignant tumor of the face. These tumors, like epidermoid cancer, tend to occur in the older age groups. They may appear in any part of the face but most often above the mouth and below the hair line and

about the ears. At the onset the tumor appears as a pearly nodule in the skin, and this nodule in the course of time breaks down to form an ulcer with rolled pearly edges. The ulcer enlarges slowly and persistently, and it may finally invade deeply, destroying underlying bone and cartilage, eventually causing hideous deformities. Despite its invasive character, a basal cell cancer rarely metastasizes.

Treatment.—Destruction of senile keratoses by electrocoagulation or excision will prevent the onset of many basal cell cancers. Because of its slow growth, the basal cell cancer is easily controlled in its early stages by adequate x-ray or radium treatment or by surgical excision.

Fig 164—Basal cell carcinoma in skin of elderly white man. Note the raised, rolled edges.

The requisite for successful treatment is destruction of all tumor cells. The cure rates of surgery and irradiation are equally satisfactory if properly applied at a reasonably early stage.

Epidermoid Cancer

Epidermoid cancers frequently begin in hyperkeratoses of the skin of the cheeks, malar and temporal areas, and ears. They are less common than basal cell cancers on the forehead, eyelids, and nose. The epidermoid or squamous cell cancer usually begins as a warty area, which later ulcerates. It tends to grow rapidly. The edges of the ulcer are indurated, undermined, and infected. These cancers may metastasize to regional lymph nodes, though only a small proportion of such tumors of the face metastasize at an early stage.

Treatment.—The primary tumor may be treated by excision or by irradiation. Preference should be given to x-ray therapy if excision will produce large deformities about the eyes, mouth, or nose. Tumors that recur after irradiation should be treated surgically. Metastatic cervical lymph nodes are best treated surgically by a complete radical neck dissection of the involved side.

Malignant Melanoma

Malignant melanomas comprise 1-2% of the malignant tumors of the body and about 20% of the cutaneous tumors. In general, melanomas of the face, neck, and scalp comprise about 30% of all melanomas. It is one of the most lethal of all neoplastic diseases, with the average 5-year survival time of all cases being around 20%.

Fig. 165—Malignant melanoma on cheek of 65-year-old white woman. Note the size of the lesion and the central ulceration.

All moles which show any of the following changes should be immediately suspected of having undergone malignant transformation: (1) increase in size, (2) change in color, especially an increase in pigmentation; (3) pain, irritation, itching, or discomfort; (4) infection or ulceration; (5) bleeding or increase in vascularity; (6) the appearance of satellite pigmented areas adjacent to the original lesion.

Malignant melanomas metastasize through the lymphatics to the regional lymph nodes or by way of the blood stream to distant organs.

It is the latter which generally defeats efforts to cure. Prior to carrying out any therapeutic therapy one should have proof of diagnosis either by means of an incisional biopsy, in the case of a larger lesion, or a punch biopsy in a smaller one.

Surgery provides the only efficient method of treatment of malignant melanoma. Melanomas are radioresistant, and this method of therapy should be used only as a palliative measure or for psychologic reasons. Extensive desiccation is to be condemned as being completely inadequate, and hormonal therapy including the use of estrogens, and pituitary irradiation, castration, bilateral nalectomy, and even a hypophysectomy have been valueless.

The surgical therapy will generally consist of a wide local excision of the primary tumor together with a resection of the regional lymph nodes. In melanomas of the face or neck in addition to wide excision of the primary lesion, a radical neck dissection on the involved side should also be carried out even if the lymph nodes are not clinically palpable. In a large percentage of these cases, metastatic malignant melanoma cells will be found within the lymphatics on histologic examination.

THE LIPS

Macrocheilia

Macrocheilia, hypertrophy of the lips, is a congenital condition, analogous to macroglossia. It is due to a lymphangioma or hemangioma accompanied by a connective tissue overgrowth. The lower lip is more frequently involved than the upper lip. The lip is firm, thickened, enlarged, and everted, causing considerable deformity. It is best treated by wedge excision of the excess tissue.

Herpes Labialis

Herpes of the lip generally follows the common cold, or exposure to sun. Cold sores begin as numerous small vesicles which later coalesce to form pustules, followed by a dry crust. The herpes should be completely healed in 1-3 weeks, unless secondarily infected. The disease is due to a virus infection. Herpes and ulcers of the lips which

not heal, under treatment, in 2-3 weeks should be regarded with suspicion. A biopsy should be taken in order to rule out the possibility of an early carcinoma.

In the early stages treatment by mild astringents, such as Witch Hazel, may be used. Bland ointments to soften the crusts should be applied later. Local application of a mild antibiotic ointment may be used with benefit.

Other Benign Lesions

The lips are subject to multiple benign conditions which are important because they may simulate an early carcinoma or are themselves precancerous in nature. They include the following conditions: hyperkeratosis, warts, papillomas, cracks and fissures, leukoplakia, and syphilis.

Hyperkeratosis is a condition characterized by the presence of fine flaky scales on the lip. The lip may bleed slightly when the scales are removed. It may be localized to a small area or may involve the entire lip. Hyperkeratosis is a premalignant condition seen mainly in people such as farmers and sailors exposed to excessive amounts of sunshine. If allowed to progress, the lesion will frequently become thickened and indurated and undergo malignant changes.

The treatment of hyperkeratosis in the early stages consists of the use of bland mild ointments to the involved area. In more resistant cases the use of low-voltage superficial x-ray therapy is of value. In more extensive and advanced cases, a mucosal stripping operation of the entire lower lip is carried out. The lip is reconstructed by advancing the mucous membrane on the inside of the lower lip and suturing it to the skin margin.

Warts and papillomas are very similar in their appearance and may be seen on the upper or lower lip. They, too, may undergo malignant changes, and for that reason they should be excised.

Cracks and fissures of the lips may be persistent and annoying, the crack tending to split open on smiling or stretching the lips. Cancer of the lip may begin in one of these fissures. If the crack or ulcer does not heal promptly on treatment by bland ointments, the fissure should be excised, and the specimen should

be examined by the pathologist. Chapped lips are associated with cold weather, the use of cosmetics, and the habit of licking the lips. Ointments should be used to keep the lips soft. Cracks about the corners of the mouth may indicate congenital or late syphilis or a vitamin B deficiency.

Leukoplakia of the lip, as elsewhere in the mucous membrane of the oral cavity, is a precancerous condition. It appears as a thick, white patch on the vermilion border of the lip similar to leukoplakia elsewhere. Histologically,

rete pegs and round cell infiltration beneath the dermis. If carcinoma ensues, the lesion becomes firm and indurated and may bleed when the surface is scraped. A biopsy must be taken in all suspicious cases. The treatment of early leukoplakia will include strict attention to the oral hygiene, elimination of infective foci in the mouth, cessation of excessive smoking, and an adequate intake of vitamin B.

Syphilis The lip is the most common site of extragenital chancre. This lip lesion is similar in appearance to a chancre elsewhere. There may be great edema of the lip, with enlargement of the regional lymph nodes. A chancre is more often found on the upper lip. Definite diagnosis is made by a search for spirochetes, by a biopsy if necessary, and by the prompt cure of the lip under antisyphilitic treatment. Treatment of the syphilis is all that is needed.

Benign tumors of the lips, such as *warts*, *polyps*, and *hemangiomas*, should be treated by the usual methods. Occasionally such lesions resemble cancer in appearance.

Cancer of the Lips (Epithelioma)

Only those cancers of the lip arising from the vermilion border or the mucocutaneous junction should be included in this category. The cancers which originate in the mucous membrane and spread to the lip grow more rapidly, metastasize earlier, and have a more serious prognosis. Cancer of the lip is a common tumor, and it comprises about 30% of oral cancers. At least 95% of lip cancers appear on the lower lip; less than 5% occur on the upper lip. Only about 3% of lip cancers

DISEASES OF THE FACE, MOUTH, AND NECK

are found in women, as shown in most statistical surveys. The majority of lip cancers are found in men over 60 years of age who have worked for years in the sun. Pipe smoking is not a proved factor in the production of labial cancer. About 40% of carcinomas occurring on the lip originate in a precancerous lesion.

Cancer of the lip may show itself as a raised, indurated lesion with a small central ulcer, as a deep hard ulcer, or as a raised warty tumor. This cancer tends to spread along the surface of the lip, rather than to penetrate early into its depth. More than half the lower lip may be attacked by the neoplasm, without deep penetration. Microscopically, the tumor is a typical squamous cell carcinoma, and the malignancy are well differentiated Grade I or II lesions.

Metastases from lip cancer occur less frequently than in other forms of oral cancer. Even in the presence of large primary cancers there may be no lymph node metastases. Of all patients with lip cancers, between 40-45% show cervical lymph node metastases on admission or develop such metastases later. Distant metastases are very rare. When metastases do occur, they are found most often in the submaxillary lymph nodes.

Treatment should not be given until a positive diagnosis has been established by the pathologist's examination of a biopsy specimen.

Treatment.—A small carcinomatous lesion of the lip (less than 1.5 cm in diameter) can be handled almost equally well by surgery or by x-ray therapy. Surgery will consist of a V-shaped excision, taking an adequate margin of tissue around the growth. In larger lesions treated surgically, the use of full-thickness pedicled flaps of the cheek or of the upper lip may be required in order to reconstruct the lower lip. The cosmetic result in many of these cases is surprisingly good. In the more superficial spreading cancer of the lip, the use of x-ray therapy is preferable. The local cancer can be controlled with little deformity by this means. Cervical metastases are best handled by a radical neck dissection. Prophylactic neck dissection to anticipate metastases in cases where none are clinically apparent is not indicated. If operation for neck metastases is inadvisable for any reason, the lymph node metastases may

be retarded by thorough x-ray therapy. In the absence of cervical adenopathy, prophylactic x-ray treatment is not advised.

THE MOUTH AND TONGUE

The mouth is lined by squamous epithelium and this epithelium is constantly exposed to minor irritation and injury. The rich blood supply of the mouth is one factor that makes its tissues resistant to the bacteria which are always present. Wounds heal promptly if serious infection is not present.

Malformations

Malformations of the mouth include cleft palate, absence of the tongue, bifid tongue, tongue-tie, macroglossia, and fissured or geographic tongue. Malformations of the jaws and irregularities of the teeth are common and varied. In more severe cases surgical treatment may be required, but most patients can be greatly improved by the orthodontist if treatment is begun at a sufficiently early age.

Tongue-tie or ankyloglossia, an abnormal fixation of the tongue, may be congenital or acquired. The congenital variety is usually caused by a short frenum. This may interfere with nursing in the infant, or it may produce speech defects in older children. Simple incision of the frenum relieves the symptoms if carried out early, and this should be done before the child begins to talk.

The term *macroglossia* refers to a chronic enlargement of the tongue, which may be congenital in origin or acquired. The congenital type may be due to a diffuse lymphangioma or hemangioma of the tongue, or it may result from a congenital arteriovenous fistula between the lingual artery and vein. The acquired lesions result from acute inflammations, as well as from various types of tumors and cancers of the tongue. An extensive cancer of the base of the tongue will occasionally manifest itself first as massive edema of the anterior two thirds of this organ.

The treatment of the congenital variety of macroglossia is usually unsatisfactory, while the acquired variety generally lends itself to antibiotic therapy, to surgery or to radiation therapy, or, in some cases, to a combination of all three methods.

Injuries

Wounds of the mouth and tongue are frequent, often caused by biting of the tongue. Bleeding may be severe and prolonged. Fractures of the jaws are usually compounded into the mouth, and this may lead to secondary infection. Teeth are often broken or completely avulsed during oral injuries.

Larger bleeding vessels should be ligated, and wounds should be sutured. Loosened teeth do not necessarily require extraction. Fractures of the jaws should be immobilized in the best possible position. If sufficient teeth are present, this is best accomplished by wiring the teeth together to splint the fracture until healing is well under way. The use of antibiotics assists in controlling infection.

Burns and scalds of the mouth and tongue, unless very deep, produce only superficial destruction of the mucous membrane and papillae. They are very painful. Deeper burns may lead to the formation of ulcers which heal with a scar. Strong acids or alkalis usually cause more destruction in the base of the tongue and the pharynx than in the anterior part of the tongue and mouth.

Inflammations and Infections

Infections in the mouth are very common, with associated spread to the regional lymph nodes or cellulitis of the surrounding soft tissues. Dental abscesses are frequently the primary site of the infection.

Stomatitis

The term *stomatitis* is applied to inflammation of the mucous membranes of the mouth. The mucous membrane becomes red, swollen, and tender, and there may be marked swelling of the face and lips. Many etiologic factors have been suggested, including vitamin deficiency, fevers, local infections from pyorrhea, or dental caries. Treatment with heavy metals such as mercury may produce stomatitis. Frequent mouthwashes, antibiotics, the removal of tartar from neglected teeth, and the care of infected teeth aid in the cure.

Aphthous stomatitis or canker appears in children or older persons as pinhead sized red or yellow spots on the edges of the tongue or

floor of the mouth. Small, very painful ulcers may form. The lesions disappear in a few days, but new crops may appear. It is said to be due to a virus. Cauterization of the cankers with a silver nitrate stick hastens recovery and relieves pain.

Vincent's Angina (Trench Mouth)

This is an ulcerative form of stomatitis due to an infection with a spirochete and a fusiform bacillus. It involves the oral mucous membrane. Smears should show the characteristic infecting organisms. Treatment includes attention to infection about teeth and gums, mouthwashes of dilute potassium permanganate or sodium perborate, and bland diet. In severe cases one may use systemic procaine penicillin 300,000-600,000 units daily.

Glossitis

Glossitis, or inflammation of the tongue, appears in several forms, and not infrequently it is associated with stomatitis or Vincent's angina. We generally recognize the following types of glossitis.

Acute superficial glossitis is characterized by burning pain, redness, and atrophy of the papillae. It may be associated with some other systemic disease, such as uremia, diabetes, Plummer-Vinson syndrome, oral sepsis, or alcoholism. One must find and treat the underlying cause.

Acute parenchymatous glossitis is a deep inflammation of the tongue which arises from penetrating or incised wounds or accidental bite of the tongue. The onset of inflammation is sudden, the tongue becomes painful and swollen, and it may protrude from the open mouth. Edema may be so severe as to interfere with respiration. Suppuration is not the rule. Treatment includes warm mouthwashes and antibiotics. If an abscess forms, it must be incised. In rare cases a tracheostomy is necessary.

Chronic glossitis occurs mainly along the side of the middle third of the tongue or on the dorsum. Ulceration may or may not be present. In some cases, especially in the milder forms of chronic inflammation, there is a combination of atrophy and hypertrophy, so that while the papillae may be fewer in number, those which remain are increased in length and

thickness. The hypertrophy may be so marked in some areas that the long papillae fall apart in rows, leaving irregular fissurelike lines 3-5 mm. deep. There is no break in the mucosa and no real fissure. Scattered patches of leukoplakia are usually present. The Wassermann reaction may or may not be positive.

Treatment of this condition may be difficult. One must pay very strict attention to oral hygiene, including the correction of dental caries and other foci of infection. Large doses of vitamin B complex must be given; alcohol and tobacco should be discontinued; mouthwashes and antibiotics may also prove valuable. If the Wassermann reaction is positive, antisyphilitic therapy must be given.

Glossitis migrans or geographic tongue. The exact etiology of this condition is not known. It occurs especially on the anterior two thirds of the tongue and is characterized by round localized areas of atrophy of the papillae, leaving a smooth red glistening surface with a white margin around it. These areas tend to enlarge and fuse to form irregular outlines simulating a country on a map. New patches are constantly appearing in different locations as the older ones fade. The treatment is similar to that outlined for chronic glossitis.

Median rhomboid glossitis is characteristically located on the dorsum of the middle third of the tongue just in front of the V of the circumvallate papillae. It is a smooth, reddish brown lesion associated with local atrophy of the papillae. It is generally painless, and the consistency is not unlike that of the rest of the tongue. Its exact etiology is not known and the lesion is ordinarily self-limiting. Occasionally it may give rise to mild discomfort, in which case it should be surgically excised.

Leukoplakia

Leukoplakia is characterized by proliferation and thickening of the mucous membrane of the tongue or mouth, without evidence of neoplastic changes. The mucous membrane is white, thick, and smooth. In later stages it may be warty or fissured. In itself leukoplakia is usually symptomless, but it should always be regarded as potentially dangerous. Cancer develops in patches of leukoplakia much more commonly than in normal mucous membrane.

Leukoplakia is seen more often in people over 40 years of age. The etiology is unknown, but chronic irritation, syphilis, poor mouth hygiene, smoking, tobacco chewing, and avitaminosis may play a part in its production.

Treatment is unsatisfactory. Oral hygiene should be improved; smoking and intake of spicy foods and alcohol should be curtailed. Syphilis, if present, must be treated. Large doses of vitamins A and B must be given, especially riboflavin. Recurrence of the leukoplakia is to be expected after treatment by excision, cauterization, or irradiation. Patients with leukoplakia should be observed regularly so that warts, ulcers, and beginning cancers can be treated at the earliest opportunity.

Benign Ulcers of the Tongue

Simple ulcers of the mouth and tongue may be caused by jagged teeth, badly fitting dentures, other trauma, or from unknown causes. They should be treated by removal of any known cause, by bland mouthwashes, or by painting with dilute solution of silver nitrate. Ulcers that fail to show signs of healing in two weeks should be biopsied. A diet high in vitamins should be prescribed.

Syphilis

Syphilis of the tongue is relatively rare today. One may see it as a *primary chancre* which differs little from a chancre elsewhere. It is generally present near the tip of the tongue. The regional lymph nodes in the submental and submandibular triangle are usually enlarged.

Mucous patches of secondary syphilis may also occur in the mouth, and in this form the infection is readily transferred to other individuals by kissing or by the use of drinking or eating utensils.

The *tertiary form of syphilis* may appear on the tongue, either in the form of a gumma or of a syphilitic glossitis. The former is often found near the midline as a soft to firm nodule which may later ulcerate. The gummatous chancre is painless and has a typical punched-out appearance, the edges are soft and overhanging, and it is usually associated with a dirty discharge of slough and pus. In the

syphilitic glossitis, the tongue has a smooth, glazed appearance associated with a moderate amount of leukoplakia and atrophy of the papillae and later ulcerates. Visible scarring may be apparent, due to the underlying fibrosis.

The blood Wassermann and biopsy will confirm the diagnosis. Specific systemic treatment will cure the local lesion.

Tuberculosis

Tuberculosis of the tongue is almost invariably accompanied by other manifestations of the disease in the larynx or lungs. The tuberculous ulcer is generally found on the tip or dorsum. The ulcer is superficial, with sloping, soft edges and a pale necrotic base, and is characteristically painful. Diagnosis may be confirmed by biopsy. Treatment of the general disease will heal the local ulcer, but excision may hasten healing and relieve pain.

Fig 166—Tuberculosis of tongue. Lesion is characteristically painful and situated on dorsum of tongue. Must exclude cancer by biopsy.

Actinomycosis

Primary actinomycosis appears rarely as a firm, painful nodule in the depths of the tongue. The nodule breaks down to form a necrotic ulcer or numerous sinuses discharging the typical sulfur granules on the dorsum of the tongue. The cervical lymph nodes are not typically enlarged. Carious teeth and pyorrhea are usually present. When the ulcer is excised the fungus may be seen in the stained sections. Excision of the ulcer, extraction of diseased teeth, and massive doses of penicillin should cure the disease.

Inflammation of the Teeth, Gums, and Jaws

Pyorrhea Alveolaris

The deposits of decayed food and tartar about the teeth at their junction with the gums allows infection to occur under the gum edges. The gums become red, pus escapes, gums recede, and from this source infection may spread to the floor of the mouth or neck. Treatment consists of cleaning tartar from the teeth and oral hygiene.

Alveolar Abscess

As a result of tooth decay, bacteria may reach the root canal, causing an abscess at the root of a tooth. The abscess may be symptomless, or there may be tenderness on pressure on the tooth. Such an abscess may lie dormant, or it may break through the thin external plate of the alveolus to produce a chronic sinus. In the lower jaw such a discharging sinus usually opens onto the skin of the chin in the midline. Extraction of the tooth generally cures the root abscess. The sinus tract may have to be completely excised.

An acute alveolar abscess may cause severe pain with swelling of the face or neck, redness of the gums, and tenderness on pressure over the affected tooth. The abscess may rupture into the mouth, or it may cause an inflammation in the face, floor of the mouth, or in the neck. Osteomyelitis of the jaw frequently results if treatment is delayed. The use of antibiotics and tooth extraction will bring about a cure.

Extension of the acute inflammation of the mouth to the neck, as a cellulitis or a cervical adenitis, is to be expected. Abscess formation is common. If the inflammation extends into the submaxillary and submental spaces, a Ludwig's angina may develop, with protrusion of the tongue and interference with respiration.

Tumors of the Mouth and Tongue

Benign Tumors of the Tongue

Dermoid cysts are found anteriorly in the midline, on the undersurface of the tongue, in the region of the raphe. As with other dermoid cysts it is lined by squamous epithelium and contains sebaceous material. The cyst can be removed readily through an oral incision.

Granular cell myoblastoma is a benign tumor that arises from embryonal myoblastic tissue. The tongue is the most common site in the body for these tumors. The tumors are characteristically small, measuring 1-2 cm. in diameter. They are firm and may occur along the lateral border or the dorsum of the tongue. Histologically, they are composed of large, rounded, or ovoid cells with acidophilic granular cytoplasm.

Fig. 167—Benign, firm sessile fibroma of tongue

Other Benign Tongue Tumors.—Rarely, innocent tumors such as lipomas, fibromas, and teratomas, containing bone or cartilage, may appear in the tongue. Hemangiomas of the capillary or cavernous types are more common, the cavernous hemangioma sometimes presenting as a pedunculated bluish mass which bleeds easily and freely.

Papillomas and warts are quite common on the tongue and are considered to be premalignant lesions. Some of these papillomas grow to cover a large area of the tongue, suggesting the possibility that cancer has already developed.

All these tumors should be treated by excision, and in all cases the tissue must be examined by a pathologist. An inflammation or hypertrophy of a lingual tonsil may be mistaken for a cancer. This tonsillar tissue is situated on the lateral border of the tongue, at its junction with the anterior pillar of the soft palate.

Benign Tumors of the Mouth

Mucous cysts are small retention cysts, containing thick mucus, which form in the mucous glands of the buccal mucosa and inner side of the lower lip. Complete excision cures the cysts.

Ranula is a cystic swelling situated in the floor of the mouth to one side of the midline. Its origin is not clear, but it appears to be a cystic dilatation of the sublingual salivary gland or of the submaxillary duct. The cyst is usually unilateral, appears in childhood, grows slowly to reach a large size, and may extend to cause swelling in the submaxillary triangle.

Treatment by complete excision is technically difficult because of the thin, delicate cyst wall and the large size of the cyst. Suture of the

Fig. 168—Lingual thyroid located in the region of the foramen cecum.

defect after incomplete removal of the ranula will cause a recurrence. Most of the cysts may be cured by unroofing the cyst and then suturing the cut edges of the cyst to the mucous membrane of the floor of the mouth, in effect a marsupialization.

Mixed cell tumors similar to those of the parotid gland occur anywhere in the mouth, most frequently on the hard palate. They are derived from the minor salivary glands present in the mucous membrane of the mouth. The tumors are well circumscribed and are covered by normal mucous membrane. They grow slowly and painlessly and are almost always

benign. They can be easily shelled out, and they do not recur if completely removed.

Torus palatinus is a hard, smooth nodular growth which measures 2-4 cm. in diameter and occurs at about the center of the hard palate where the two maxillas are fused in the midline. It is a true osteoma of the maxilla and is generally covered with normal mucous membrane. The lesion has no special clinical significance, except that it may be mistaken for a malignant bone tumor or may interfere with the proper fit of a dental plate. It can be surgically excised if necessary.

Torus mandibularis is a similar exostosis occurring on the inside of the lower jaw. It may occur in the midline, or it may be present symmetrically on either side of the midline. No treatment is necessary unless the lesion interferes with lower dentures.

Fig 169—*Torus palatinus*. A benign osteoma of the hard palate.

Epulis is a not uncommon tumor of the mouth and is seen most frequently in children and young adults between the ages of 10 and 20 years. It occurs on the alveolar ridges at the gingival margins of the teeth, often where teeth have been extracted, and is said to arise from the alveolar dental periosteum. Such tumors are usually covered with mucous membrane and may have a narrow pedunculated attachment or may be sessile and spread over the gum surface for some distance, hiding the crowns of adjacent teeth. The consistency of the tumor is soft, and it has a red or reddish brown color. The epulis is almost always a

benign tumor which grows slowly and painlessly. Histologically it is composed of many multinucleated giant cells in a dense fibrous stroma.

The treatment is surgical. If not completely removed, the lesion is likely to recur. It may be necessary to extract adjacent teeth, especially if these have been loosened from their sockets by the pressure of the tumor.

Fig 170—Benign giant cell epulis of the gum.

Malignant Tumors of the Mouth

Cancer within the mouth is common, and it may involve the tongue, cheek, gum margins, floor of the mouth, palate, or tonsils. Cancers in these different areas of the mouth vary somewhat in rapidity of growth, malignancy, and tendency to form metastases. In all cases the disease is so malignant and dangerous that the need for early diagnosis and prompt, adequate treatment cannot be overemphasized.

Cancer of the mouth accounts for about 4% of all cancer in man, and occurs in the male four or five times more commonly than in the female. The neoplasm, usually occurring after 40 years of age, is most common between the ages of 50 and 70 years.

Although the etiology of cancer is unknown, intraoral cancer is generally found in association with poor mouth hygiene, rough carious teeth, badly fitting dentures, leukoplakia, and syphilis. There is often a history of excessive smoking or of tobacco chewing. Chronic actinomycosis with glossitis and stomatitis may also be present.

About 90% of mouth cancers are of the epidermoid type, arising from the squamous epithelium which lines the mouth and covers the tongue. Adenocarcinoma may arise from mucous or minor salivary glands, and such cancers are most frequently found in the palate. Melanocarcinomas infrequently appear in the mouth, usually on the palate and alveolar ridge. Lymphosarcomas may originate about the base of the tongue, tonsils, and oropharynx. Most of these tumors tend to metastasize to regional lymph nodes.

A. Cancer of the Tongue

Cancer of the tongue is the most frequent type of intraoral cancer. It comprises approximately 25% of all malignant tumors originating from within the mouth. For clinical reasons we generally divide the tongue into two main areas—the mobile anterior two thirds of the tongue extends from the tip to the vallate papillae, and the base of the tongue extends backward from this point to the hyoid bone. The squamous epithelium which covers the tongue is firmly adherent to the underlying muscle. The lymphatics of the anterior part of the tongue drain to the submental and submaxillary triangles and to the internal jugular chain of lymph nodes. The lymphatics of the base of the tongue, in common with the oropharynx, drain to the subdiaphragmatic lymph node and to the lower internal jugular chain. There are lymphatic communications across the midline of the tongue, especially at the tip and base of the organ, so that cancers of the tip, dorsum, or base of the tongue frequently metastasize to both sides of the neck. However, when the growth is confined to the lateral margin of the tongue, unilateral spread only is to be expected. Cancer of the anterior two thirds of the tongue is predominantly a disease of males, occurring five to six times more commonly in males than in females. Cancer of the base or posterior third of the tongue affects both sexes almost equally. It is interesting that the majority of tongue cancers, approximately 60%, occurs on the lateral edges of the middle third of the tongue, about 30% occurs on the posterior third, while the remainder occurs on the anterior third or dorsum of the tongue.

Cancer of the tongue begins as an indurated area or a fissure in a patch of leukoplakia, as a papilloma, or as a small ulcer. The earliest lesions look so innocent that cancer is often not suspected. Central necrosis and ulceration of the cancer occur early. Severe pain is not usually a symptom in a small tongue cancer, and this fact is responsible for the delay in diagnosis of cancer of the base of the tongue. The cancer begins most often on the lateral margins or undersurface of the middle third of the tongue. The primary lesion, if untreated or uncontrolled, does not long remain superficial but spreads as a deep burrowing indurated ulcer. In the later stages severe pain, in *section*, tongue fixation, salivation, cervical metastases, and terminal hemorrhage present a horrible picture.

Examination of the tongue should include palpation, as well as inspection, as the area of induration may be more extensive than might appear from inspection alone. Palpation is especially useful in examination of tumors of the base of the tongue.

Cervical metastases appear early in tongue cancer, and they are present in about 40% of patients when first examined. Cervical metastases can be expected at some stage in 65-70% of cases under observation or treatment. Distant metastases are considered rather uncommon, but autopsies frequently demonstrate their presence.

The appearance of the lesion, its progressive growth, the age of the patient, leukoplakia and enlarged cervical lymph glands may make positive diagnosis of cancer easy. Vincent's angina, traumatic ulcer, papilloma, tuberculosis, or gumma must be considered in the differential diagnosis. Biopsy, which should be done early, is necessary to settle the diagnosis. A positive Wassermann reaction does not eliminate the probability of cancer, and, indeed, mouth cancer is much more common in syphilitics than in the general group of the population. All suspicious tongue lesions should be regarded as cancer until proved innocent by biopsy.

Treatment.—Much may be accomplished by prophylaxis to prevent oral cancer. Removal of small areas of leukoplakia, dental care, and the treatment of syphilis are indicated.

Mouth Cancer and the Dentist, American Cancer Society, Inc.*

When tongue cancer has begun, treatment includes attack on the local lesion and on the metastases. In the advanced cases only palliative treatment is advisable.

Surgery and irradiation are the two principal methods employed in the treatment of cancer of the tongue. Whatever method is used will depend to a large extent on the experience and skill of the attending consultant, the size and location of the lesion in the tongue, the presence or absence of cervical metastases, and the general condition of the patient.

Radiation therapy is suitable for (1) patients who refuse surgical procedures, (2) aged and debilitated patients who are poor operative risks, (3) patients with small to moderate-sized growths on the tongue without evidence of cervical lymphatic spread, and (4) patients with tumors involving the base of the tongue.

The main methods of radiation therapy consist in the use of the following procedures either alone or in combination with one another: (1) external x-ray, (2) peroral x-ray therapy using a suitable sized cone, and (3) interstitial irradiation using radon seeds or radium needles.

The reason that cancers of the base of the tongue tend to be treated by means of irradiation alone is that such lesions are relatively inaccessible for surgery. Furthermore, they are generally more anaplastic and therefore more radiosensitive than lesions situated on the anterior two thirds of this organ.

The cases most suitable for surgery are as follows:

1. Small cancers measuring up to 3 cm in diameter. Such lesions situated on the lateral border or on the tip of the tongue can be removed quite adequately by a V excision, including a wide margin of normal-appearing tongue tissue on either side.

2. All cancers of the tongue in which there is evidence of metastases to the cervical lymph nodes. For such patients, the proper treatment includes complete destruction of the primary growth simultaneously with removal of the lymphatic tissue and lymph nodes draining the tumor area. The operation will consist of a radical neck dissection, together with a resection of the primary lesion on the tongue, generally carried out in continuity. This is done in one of two ways:

(a) The neck dissection is performed and the mandible, floor of mouth, and half of the tongue are removed *en bloc*.

(b) Here the neck dissection is completed, and the floor of the mouth and tongue muscles are loosened in the neck. The neck wound is closed, and the hemiglossectomy is executed through the mouth. The resected neck tissues are pulled up through the mouth, or the tongue is pulled down into the neck so that there is actually an *en bloc* dissection without removing the jaw. This is the "pull-through" operation of Ward.

3. All cases where the mandible is involved by growth. The use of radiation therapy can result in marked osteonecrosis of the mandible with considerable amount of morbidity and with little chance of controlling the cancer in the bone.

4. Failure or recurrence following radiation therapy will certainly require radical surgical attempts in an effort to control the disease. Hemiglossectomy and even total glossectomy may be required for patients who fail to respond to radiation or in those in which the tumor recurs after thorough irradiation.

As we have already implied, the most effective treatment for metastatic cervical lymph nodes from a primary cancer in the tongue is a complete radical neck dissection. In a small percentage of cases where there are metastases to both sides of the neck, a bilateral radical neck dissection will be required. The neck dissection may be carried out as a later and separate procedure, where the primary is already controlled, or as an associated procedure as mentioned previously. There is no uniform agreement regarding the advisability of carrying out a prophylactic neck dissection in cancer of the tongue. The decision in any given case will depend upon the clinical setting which includes many factors such as the age of the patient, the size and location of the primary tumor, the ability of the patient to attend frequent follow-up visits, and the histologic grade of the lesion.

B. Other Malignant Tumors of the Mouth

Other malignant tumors in the mouth may arise from the floor of the mouth, the upper or lower alveolar ridge, the buccal mucosa, or

the hard or soft palate. The lymphatic drainage from these areas is primarily to the sub-mandibular and the upper cervical lymph nodes.

The majority of the cancers are epidermoid in type arising from the surface epithelium. Occasionally one finds an adenocarcinoma arising from the minor salivary gland tissue present within the oral mucous membrane. On very rare occasions a malignant melanoma may be seen arising either from the alveolar ridge or from the hard palate.

Oral cancers generally begin in an area of leukoplakia either as a small warty lesion, as a larger fungating tumor, or as an ulcerating and infiltrating neoplasm. A biopsy will readily establish the diagnosis.

Treatment.—The treatment in any given case will depend on several factors, including the age and general condition of the patient, the location and extent of the primary tumor, the presence or absence of cervical lymph node metastases, and the proximity of the lesion to bone or to its actual involvement of bone. In many of the smaller lesions, radiation therapy or surgery will yield equally excellent results. In larger tumors adjacent to or involving bone and in cases where there is established lymphatic metastasis in the neck, radical surgery is to be preferred. This will consist of wide excision of the primary tumor combined with a partial resection of the upper or lower jaw, as the case may be, and a radical dissection of the lymphatic tissue of the involved side of the neck.

THE PHARYNX

The pharynx is a cylindrically shaped tube that is wide above and narrow below. It extends from the base of the skull above to the level of the 6th cervical vertebra below. The pharynx is generally divided into three parts:

- 1 The nasopharynx extends upward above the level of the soft palate to the base of the skull
- 2 The oropharynx is that part of the pharynx between the soft palate above and the tip of the epiglottis below
- 3 The hypopharynx is that part of the pharynx that extends below the tip of the epiglottis and includes the pyriform sinus on

either side. Anteriorly the hypopharynx communicates with the larynx, while posteriorly it becomes continuous with the esophagus

Inflammatory Lesions

Tonsillitis

This may be acute or chronic in type. In the acute type the symptoms are those of sore throat, difficulty in swallowing, chills, fever which may go up to 103°-104° F., and general malaise. The responsible organisms are usually hemolytic streptococci. The tonsil itself

Fig. 171.—Anatomy of the pharynx and larynx

generally becomes enlarged and appears red and swollen, and there may be grayish white patches of exudate on the surface or within the tonsillar crypts. The upper jugular lymph nodes which drain the tonsil become acutely enlarged, painful, and quite tender.

The treatment of acute tonsillitis is conservative and consists in the use of large doses of a suitable antibiotic and the use of warm saline or soda bicarbonate mouthwashes, together with the use of aspirin compound to control the pain and lower the temperature

Peritonsillar abscess or quinsy, a serious complication of acute tonsillitis, consists in suppuration outside the capsule of the tonsil and, in most cases, is situated in the tissue of the soft palate above the tonsil. The symptoms are those of acute tonsillitis, only more severe. Examination will readily show that the palate on the affected side is congested and bulging, and the uvula may be quite swollen, edematous, and pushed across toward the opposite side. In addition to the methods recommended above for the treatment of acute tonsillitis, one must perform surgical incision and drainage of the abscess. This is usually followed by immediate relief of symptoms and rapid recovery.

Retropharyngeal Abscess

Two forms of retropharyngeal abscess are generally recognized—the acute and the chronic. The acute abscess is due to pyogenic infection in the retropharyngeal lymph nodes, which occurs most often in children but can be seen occasionally in adults and is generally secondary to some focus of infection in the mouth or throat. Suppuration of the lymph node ensues with subsequent abscess formation.

The acute type may also be seen as a complication following gastroscopy and esophagoscopy when a periesophageal infection results from damage to the mucosa of the upper

Fig. 172—A, Acute retropharyngeal abscess situated anterior to the prevertebral fascia and to one side or other of the midline.

B, Tuberculous retropharyngeal abscess secondary to tuberculosis of a cervical vertebra. The abscess is situated behind the prevertebral fascia and may bulge the pharynx in the midline.

Chronic tonsillitis is a condition which occurs predominantly in children and is associated with hypertrophy of the adenoids. It generally manifests itself by a chronic hyperemia of the pillars. The tonsil at times may be small, while at other times it is larger than normal. It is usually smooth and pale in appearance. The upper cervical lymph nodes are frequently palpably enlarged.

Treatment, consisting of tonsillectomy, is necessary when (1) the tonsils are large enough to cause respiratory or speech difficulty, (2) there are recurrent sore throats, and (3) there are systemic infections traceable to a focus in the tonsil.

Esophagus. The usual site of injury is in the postcricoid region where the thin esophageal wall may be compressed between the lower cervical vertebral bodies and the rigid endoscope. This is particularly likely to occur in patients with anterior bony spurs due to osteoarthritis. The injury, which may be a simple bruising of the wall or an actual pressure necrosis, results in a perforation of the wall and a resultant retropharyngeal or retroesophageal infection.

The acute abscess occurs in front of the prevertebral fascia and behind the buccopharyngeal fascia. Such an abscess tends to remain on one side or the other of the midline because of the attachment of the buccopharyngeal fascia

Fig. 173 --A, Large, acute right retropharyngeal abscess. Note the air fluid level. Tracheotomy required because of tracheal compression.
 B, Secondary abscess in the right superior mediastinum, caused by downward extension of the infection between the second and third layers of the deep cervical fascia. Both abscesses were found to be in direct communication at operation and were drained through a single incision in the right neck along the anterior border of the sternomastoid muscle. The middle space was entered by incising the second layer of deep fascia anterior and medial to the carotid sheath.

to the prevertebral fascia in the midline. This abscess, lying between the second and third layers of the deep cervical fascia, if left untreated, will track down to form a secondary collection in the superior mediastinum.

The symptoms to be expected are fever, swelling in the pharynx, difficulty in breathing, supraclavicular tenderness, and more or less toxic reactions. Clinical swelling of the neck may develop but is not an early feature. X-ray of the neck may show the presence of gas within the soft tissues, and this is almost pathognomonic of either a frank tear or a slow leak from a minute hole in the esophagus.

Treatment.—Before treatment is initiated, an x-ray should be taken of the cervical vertebrae to determine whether or not tuberculous disease is present. A history of a previous endoscopic procedure should immediately raise the question of a possible periesophagitis, and x-ray may show the presence of gas and/or fluid in the soft tissues of the neck. For the patient with an acute abscess, immediate conservative therapy should be instituted, giving him large doses of antibiotics and forbidding all fluid and food by mouth. If there is a demonstrable fluctuant abscess in the posterior pharynx, then the patient should be taken to

Fig. 174—Lateral cervical approaches to retropharyngeal abscess

A, Lines of incision

B, Arrows indicate the pathway to the focus I, posterior approach, II, anterior approach

The second type of retropharyngeal abscess is the chronic type and is generally due to tuberculosis of cervical vertebrae. This abscess lies behind the prevertebral fascia and may present into the pharynx in the midline, in contrast to the acute abscess which is lateral in position. Such an abscess spreads behind the prevertebral fascia and may point on either side of the neck behind the sternomastoid muscle. Occasionally it may track down behind the fascia into the posterior thorax.

the operating room, where, under endotracheal anesthesia, the fluctuant abscess is opened through the mouth. The patient's head should be lowered and the pharynx well packed off in order to prevent aspiration of pus. A tracheostomy set should be on hand in case of need. Occasionally an abscess may be incised without anesthesia.

Unless there is a frank tear in the esophageal wall, most cases of periesophagitis following endoscopy will respond to conservative treat-

DISEASES OF THE FACE, MOUTH, AND NECK

ment, as outlined above. A minority of these cases, however, may go on to frank suppuration, and then surgical drainage becomes necessary. The usual approach is through a small incision along the posterior border of the sternomastoid muscle, just below the cricoid level. Once the deep cervical fascia has been reached, the finger easily passes medially along the front of the prevertebral fascia. This leads directly to the retropharyngeal space at the level where trauma usually occurs. After sucking out the pus from the abscess cavity, a rubber tube is passed along the track and the skin approximated around the tube. Alternately, where there is evidence of tracking down of the infection into the superior mediastinum, a cervical mediastinotomy becomes necessary, and this is best carried out by a single incision in the neck running along the anterior border of the sternomastoid muscle. The retropharyngeal space is entered by incising the second layer of the deep cervical fascia, anterior and medial to the carotid sheath (Fig 174, A, B).

In the chronic type of retropharyngeal abscess with evidence of bone disease, the abscess should be aspirated through the side of the neck or the pus evacuated by an incision behind the sternomastoid muscle with resuture of the wound. The usual systemic treatment of tuberculosis should then be vigorously instituted.

TUMORS OF THE PHARYNX

Tumors of the Nasopharynx

Benign Nasopharyngeal Fibroma.—This usually occurs in young males aged 6-25 years and is rarely seen after the age of 30 years. Histologically, the lesion is composed of a mixture of vascular and fibrous connective tissue.

The tumors arise from the walls of the nasopharynx and are encapsulated and generally attached by a pedicle at the point of origin. The early symptoms include nasal obstruction and bleeding because of their vascularity. Although benign, these tumors can, because of continued growth and pressure, cause marked displacement of the eyes, cheeks, and surrounding tissue.

Treatment.—Small tumors can be removed through the nares. Medium-sized lesions on a pedicle may be removed by means of a cautery

snare utilizing a combination approach through the nose and through the mouth. Larger tumors are best reached by means of a Ferguson incision on the face, going through the antrum to reach the nasopharynx. If not completely removed, the lesions can and do recur. If residual tumor is left, it should be treated either by x-ray or direct radium application.

Radiation therapy alone is not effective in completely eradicating nasopharyngeal fibroma. Extensive radiation for such benign tumors should not be given because of the danger of early or late osteonecrosis of the base of the skull with secondary meningitis. It has been postulated that these tumors may be related to excessive estrogens, and for that reason many of them have been treated with testosterone propionate. The results with this method of treatment have proved somewhat disappointing.

Cancer of the Nasopharynx.—The majority of malignant neoplasms of the nasopharynx consist of epidermoid carcinoma and lympho-adenocarcinomas arising from the mucous and minor salivary glands. This disease occurs predominantly in males and has a special tendency to occur in the Chinese male. The lymphatics from the nasopharynx drain primarily to the spinal accessory chain situated in the posterior triangle of the neck. The early symptoms of nasopharyngeal cancer may be lacking, and the first evidence may be a large hard lymph node in the posterior triangle of the neck. Later, deafness and tinnitus may occur because of encroachment of the disease on the eustachian tube, or there may be nasal obstruction and bleeding. The disease may later erode the base of the skull to involve the 6th cranial nerve and produce paralysis of the external rectus muscle of the eye. The 3rd, 4th, and 5th cranial nerves may be later involved.

Treatment.—Surgery is not indicated in cancer of the nasopharynx because of the relative inaccessibility of the region to an adequate surgical approach. Furthermore, these tumors are usually highly anaplastic and, in general, radiosensitive. The treatment, therefore, is primarily by irradiation, utilizing a combination of external radiation therapy through multiple ports, generally supplemented by intracavitary radium or radon.

Tumors of the Oropharynx

These include lesions arising in the posterior and lateral walls and those arising from the tonsil and tonsillar pillars, but do not include those arising in relation to the base of the tongue or to the extrinsic larynx. The most frequent and important tumors arising in this region are of a malignant nature.

Cancer begins either on the lateral or the posterior wall or both. Early symptoms are lacking, and not infrequently the first symptom is a large metastatic lymph node in the neck. In other cases the patient may complain of a mild irritation in the throat or of slight dysphagia. Later, as the tumor enlarges, dysphagia becomes more marked, difficulty in breathing and hoarseness are still later manifestations.

The majority of the tumors are epidermoid cancers. The treatment is by means of external irradiation given through two or more ports.

Cancer of the Tonsil

Next to cancer of the laryngopharynx, cancer of the tonsil is the common malignant tumor of the upper air passages, and it comprises about 25% of all cancers. Malignant tumors of the tonsil may be carcinomas, lymphoepitheliomas, or lymphosarcomas. The *epidermoid cancer* is the commonest form, and it appears as an ulcerating tumor of the tonsil, spreading to the soft palate and the pillars of the tonsil. This cancer is rather undifferentiated and radiosensitive, and it gives early lymph node metastases.

The *lymphoepithelioma* is usually a smooth tumor, showing little ulceration or spread to the palate. Lymph node metastases appear early, and there may also be extension to the lungs, mediastinum, liver, and bones. This tumor is extremely radiosensitive.

Lymphosarcoma does not ulcerate until late, but it may reach a large size in the tonsil. Enlarged cervical lymph node metastases accompany the tonsillar hypertrophy, and the disease may give a general lymphadenopathy as in lymphosarcoma elsewhere. Here, too, the disease is very radiosensitive.

Treatment—Since the majority of the malignant tumors occurring in the tonsil are highly radiosensitive, it follows that the best form

of treatment is radiation therapy. Even cervical lymph node metastases in cases of lymphoepithelioma and lymphosarcoma may be well handled by means of irradiation. Surgery is generally reserved for recurrences following adequate x-ray treatment. Cases of squamous cell carcinoma of the tonsil may prove to be much more difficult to control by means of irradiation. Primary surgery is especially indicated in cases of squamous cell carcinoma in which there is evidence of cervical lymph node metastases. In such cases the treatment will consist of a radical neck dissection combined with a resection of the ascending portion of the ramus of the mandible together with the tonsillar region in continuity.

Tumors of the Hypopharynx

Here, also, the most frequent and important tumor is cancer. Except for lesions arising on the posterior wall of the hypopharynx, most of the cancers in this region are best considered as lesions of the extrinsic larynx. Cancers of the posterior wall of the hypopharynx usually spread diffusely and tend especially to extend down toward the esophagus. The symptoms include vague discomfort in the throat on swallowing, in the early cases, and frank dysphagia later. Metastases to the deep cervical lymph nodes occur relatively early and at times may be the only symptom.

Treatment may be carried out either by means of external x-ray or by surgery. The Trotter or Wooley operation of resecting the hypopharynx and part of the cervical esophagus may be tried, with reconstruction of the pharynx in several stages by means of skin flaps. Another method of reconstruction consists of utilizing a tubular split thickness skin graft wrapped around a wire mesh or plastic stent. It may or may not be necessary to sacrifice the larynx, depending on the extent of the disease.

THE LARYNX

Benign Tumors

Papillomas of the larynx are the most frequent of all benign growths. They may occur in children as well as in adults and are definitely precancerous in nature. Other benign

Fig 175—Carcinoma of the right vocal cord.

Fig 176—Carcinoma destroying the left vocal cord with subglottic extension

tumors include specific granulomas due to syphilis, tuberculosis and the like, and the non-specific granuloma which is due to chronic irritation or to an inflammatory condition. Fibroma, lipoma, hemangioma, chondroma, and cysts are other rarely encountered benign tumors.

The *symptoms* of benign laryngeal tumors include hoarseness or huskiness of the voice. In larger lesions dyspnea results due to obstruction of the airway.

The *treatment* of benign lesions of the larynx is removal through the mouth by means of the direct laryngoscope and proper forceps.

Malignant Tumors

Cancers of the larynx comprise about 2% of all human cancers. Over 90% of the cases occur in males. We generally divide lesions in this region into two groups:

1. Cancer of the intrinsic larynx, which includes all those arising on the vocal cords, ventricles, and in the subglottic region.

2. Cancer of the extrinsic larynx, which includes those arising on the epiglottis, the aryepiglottic fold, the upper surfaces of the ventricular band, or in the postcricoid region.

The symptoms of laryngeal tumors will depend upon their exact site of origin. Hoarseness is the earliest symptom in cancer of the intrinsic larynx. Later there is dyspnea due to a diminished airway, and finally complete aphasia. Metastases to the cervical lymph nodes occur only late in the disease.

Fig 177—Carcinoma involving the base of the epiglottis

In cancer of the extrinsic larynx, the early symptoms are similar to those mentioned for hypopharyngeal tumors. Hoarseness occurs later as a result of secondary involvement of the glottic region. Metastasis to the cervical lymph nodes is a prominent and early occurrence and in a small group of patients may be the first symptom of an extrinsic laryngeal cancer.

The diagnosis of cancer should always be confirmed by biopsy, usually carried out through a laryngoscope.

The *treatment* for early cancers of the intrinsic larynx confined to the vocal cord can be either by a partial laryngectomy (laryngofissure) or by means of fractionated radiation.

therapy. Once the lesion has extended beyond the confines of one side of the intrinsic larynx and has crossed the midline to the opposite side or has extended down into the subglottic region, the most effective treatment is a total laryngectomy.

Cancers of the extrinsic larynx have, in recent years, been treated primarily by a total laryngectomy, and the results with surgery have been much better than with irradiation. When there are associated metastatic lymph nodes in the neck, a radical neck dissection should be performed in continuity with a total laryngectomy.

Following a total laryngectomy a fairly good esophageal voice can be easily learned by most patients. Others prefer to use an artificial larynx, of which there are several varieties on the market.

CANCER OF THE MAXILLARY SINUS

Cancer of the maxillary sinus occurs in males and females in the ratio of about 2:1 and occurs most frequently in the age group 60-70 years. The most frequent variety of cancer in this area is epidermoid carcinoma. Occasionally adenocarcinoma, lymphosarcoma, or fibrosarcoma occurs.

The lymphatics of the antrum communicate with those of the nasal fossa and they end in the retropharyngeal, submaxillary, and the internal jugular lymph nodes.

Most cancers of the antrum begin in the floor of the sinus near the tooth roots. As it grows, the tumor expands the anterolateral wall and the floor of the sinus, causing swelling in the cheeks, palate, and upper gum with loosening of the bicuspid and anterior molars.

The early symptoms may be a toothache or vague pain or discomfort in the cheek. Nasal obstruction or a bloody discharge from the nose may also occur. Later there is invasion of the anterior or nasal walls of the antrum or of the hard palate with swelling of the cheek, and obliteration of the gingivobuccal gutter. Where the tumor arises on the roof of the antrum, there is early invasion of the floor of the orbit, with displacement of the eye upward and outward.

Metastases rarely occur except during the late stages of the disease when the local

growth has not been controlled. The patient is more likely to die from the local effects of the disease than from metastases.

Diagnosis is made primarily by x-ray examination of the antrum and needle puncture biopsy.

Treatment.—Radiation therapy has been used for many years, but the results and the complications of treatment have been discouraging. More recently the trend has been toward the use of radical surgery. If the growth is confined to the antrum, especially the floor, wide resection of the maxilla can be carried out with little risk and little deformity to the patient. If the floor of the orbit is invaded, an exenteration of the orbit should also be included. The surgical approach for these tumors is generally through a Ferguson incision on the face. The resulting defect is covered with a split-thickness skin graft. X-ray or radium is employed in local recurrences. Electrocoagulation of the tumor followed by radium or x-ray has yielded fairly good results in some centers.

THE JAWS

Fractures
(See pages 248-252)

Infections

Infections within and about the jaws arise, in the majority of cases, from local infection within the teeth or sinuses. In only a very small percentage of cases is the infection blood borne from some distant focus in the body. The periodontal membrane or the pulp canal of the tooth is generally the primary focus of infection, which may then spread by direct extension to involve the bone and adjacent soft tissues. In the majority of cases of osteomyelitis of the jaw, there has been recent extraction of an acutely infected tooth. Other less frequent causes of osteomyelitis of the jaw include compound fracture of the mandible, infection of the maxillary antrum, and mental furuncle with direct extension by the lymphatics into bone, as a blood borne infection from a more distant focus of infection, or it may be a result of radium or x-ray necrosis of bone following irradiation of intraoral cancer.

DISEASES OF THE FACE, MOUTH, AND NECK

The signs and symptoms of an acute inflammation of the jaw are those of local pain, cellulitis, and swelling. Associated with this are fever, chills, and leukocytosis.

In the mandible the inflammation may rapidly spread to involve the soft tissues of the submaxillary triangle and upper neck, resulting in a Ludwig's angina with its dangers and complications.

The treatment is, first of all, prophylactic, consisting of the judicious use of radiation therapy in the treatment of head and neck cancer. It is especially important to treat dental sepsis and even to extract all teeth within the field of irradiation prior to commencing treatment. It is wise to provide antibiotic coverage in any case where there is to be a tooth extraction for pulp canal or periodontal infection.

The treatment of an established case of osteomyelitis of the jaw requires the immediate use of large doses of penicillin. Surgery is only performed to drain local soft tissue abscesses or to carry out resection of necrotic bone as demonstrated on the x-ray film.

Tumors

Benign and malignant tumors of the upper and lower jaws are uncommon clinical entities, but they are important because they may interfere with the proper functions of eating and speaking, because of their cosmetic appearance and because if not properly treated they may prove fatal to the patient. Most of the tumors are benign in nature. The classification of tumors of the jaws is quite extensive and only the more important and those most frequently encountered.

Benign Tumors and Cysts

It is not always possible to differentiate between a single or multilocular cyst and a benign tumor. In both conditions there is generally a radiolucent area, or there are areas with irregular outlines. Benign tumors tend to expand the jaw as they grow, and the cortex is thinned out or destroyed by pressure, but it is not invaded as in the case of a malignant growth. There is neither periosteal reaction nor soft tissue change in the case

of benign tumors and cysts. The majority of benign lesions are asymptomatic in their early stages. Usually the patient's only complaint is a localized swelling over the jaw. The mandible may be so destroyed that a spontaneous fracture may occur. When the other symptoms appear, they are usually the result of pressure of the tumor on adjacent structures or secondary infection. A vague ache or pain may then be a complaint.

The diagnosis is established by a combination of clinical examination, x-ray study, and biopsy. It is vital to differentiate the benign from the malignant lesions, and while x-ray studies will frequently succeed in this regard, it is a biopsy that will finally establish the exact histologic diagnosis and will thus enable the surgeon to plan his treatment properly.

Odontogenic Cysts.—True cysts arising from dental epithelium are called odontogenic cysts. The cysts contain fluid or a semifluid material and have a definite epithelial lining or membrane. The following types occur.

Dentigerous cysts are the most common cysts of the jaw and are always associated with nonerupted teeth which can be readily seen on an x-ray. In the early stages there are no suggestive symptoms other than the nonerupted teeth. Later, as the cyst grows, there is expansion of the jaw, and the cortex becomes so thin that it will dent like a ping pong ball on pressure. The cyst lining is formed from the outer wall of the enamel organ.

In follicular cysts, the first symptom is generally a painless swelling of the jaw, which occurs mainly in young patients. This type differs from a dentigerous cyst in that there are no teeth in the cyst, and the mouth will contain the normal number of teeth if too is lined by epithelium derived from the dental epithelium.

Radicular cysts almost always occur around the root of a tooth and thus differ from dentigerous or follicular cysts. Occasionally they occur at the lateral surface of the root. The cysts contain a straw-colored watery or thick mucoid fluid. On the x-ray film one will generally see a translucent area of varying size, with well-defined margins at the apex of the tooth. The lesion may be large and involve many teeth or invade the antrum

Fig 178—Large dentigerous cyst involving the posterior portion of the left side of mandible
Note the unerupted left first molar tooth

Fig 179—Large cystic type of adamantinoma

Occasionally the cyst may become secondarily infected and rupture into the mouth, discharging a purulent material.

Treatment.—The treatment of all odontogenic cysts is surgical. A mucoperiosteal flap is first raised over the tumor, and the bony wall, if present, is removed. The cysts are then curetted free of their contents and lining membranes and packed open. The mucoperiosteal flap may be partially resutured. The retained tooth in a dentigerous cyst and the involved tooth or teeth in a radicular cyst must be extracted. The packing is removed over a period of several days, and the cavity is allowed to fill with blood and to organize.

Benign Tumors of the Mandible.—Adamantinoma or ameloblastoma arises from the enamel organ epithelium or the ameloblast. The most common symptom is a painless swelling of the jaw which may be continuous for as long as 15-20 years. Because of the lack of pain and the slow insidious growth, the tumors may attain a very great size. They are more frequently found in the mandible than in the maxilla. The tumor is generally irregular in shape and on the roentgenogram may show multilocular cystic cavities. The walls of the cystic cavities may be thinned out and crepitate on palpation. Although the spaces appear cystic, most of them are filled with a solid cellular growth, while the others contain a clear yellow fibrinous or mucoid fluid. While one can frequently suspect the diagnosis of an adamantinoma from careful roentgenologic study, the final diagnosis must always be made by microscopic examination.

Treatment.—It was once felt that these lesions could be treated just as one would treat ordinary cysts of the jaw, that is, by removal of the abnormal epithelium and curettage of the cystlike spaces. This treatment, however, is inadequate and is generally followed by recurrences which will require further treatment or which, in a small number of cases, may become malignant. In small tumors one may carry out a local resection of the mandible, removing a margin of normal bone around the tumor, and yet retain enough of the mandible to prevent fracture and maintain normal bony contour. In larger tumors or in tumors where there is perforation of the bone and extension into soft tissues, one must

carry out a radical resection of the involved mandible. Reconstruction of the mandible by means of bone graft or by various metal prostheses may be used.

Fibrous and Granulomatous Tumors of the Jaw.—This group includes the following lesions: benign giant cell tumor, solitary and generalized osteitis fibrosa, fibrous osteoma or ossifying fibroma, and fibrous dysplasia of bone. These are all destructive central lesions involving the jaws of young people and are considered to be benign. Only rarely do they

Fig. 180.—Benign ossifying fibroma of the mandible.
Note the cystic appearance of the lesion.

become malignant, and seldom do they occur after 30 years of age. Although many of these growths are described as cystic by the radiologist because they appear as radiolucent areas in the bone, the great majority are not truly cystic but fibrous or granulomatous in nature. The cysts, if present, do not have an epithelial lining, as found in cysts of odontogenic origin. The diagnosis is made by means of a careful radiologic study and biopsy. Even radiologically these lesions may appear so much alike that it is impossible to distinguish them with absolute certainty.

These lesions are characterized by a replacement of the central bony structure with a soft tissue which causes marked thinning of the cortex as expansion progresses. In giant cell tumors the growth is largely granulomatous, with many phagocytic and multinucleated giant cells and some fibrous stroma and evidence of hemorrhage. In the localized osteitis fibrosa, the growth is largely fibrous, with some osteoid but no normal bone formation and no giant cells. The serum calcium and phosphorus are normal. The generalized osteitis fibrosa is a manifestation of hyperparathyroidism and is associated with an elevation of serum calcium, a decrease in serum phosphorus, and an increase in the alkaline phosphatase level in the blood. Fibrous osteoma or ossifying fibroma is characterized by a dense fibrous stroma in which there are scattered new bone trabeculae. In fibrous dysplasia there is a proliferation of small spindle cells in a loose connective tissue stroma. In other areas the stroma is composed of dense collagen with little or no cellularity. There may be foci of osteoid formation and also of hyaline cartilage.

Treatment.—Because of the benignancy of these lesions, they should be treated, on the whole, by conservative surgical means. This will consist of simple excision of the growth or curettage of the lesion, with packing of the excavation with bone chips, and occasionally by partial resection of the mandible. In generalized osteitis fibrosa, one must treat the hyperparathyroidism, whether due to an adenoma or hyperplasia of these glands.

Chondroma and Osteochondroma.—Cartilage tumors of the jaws are rare. They occur

in adults and may present with symptoms of pain, swelling, and disability. Radiologically they appear as translucent lesions with or without scattered foci of calcareous tissue. These lesions are capable of recurring or of becoming malignant, and for that reason they should be excised in a radical manner, including a zone of the normal surrounding bone.

Malignant Tumors

Malignant tumors of the jaws may be primary or secondary. The former are by far the most frequent variety. The secondary type may be the result of metastases from cancer of the prostate, thyroid, breast, lung, kidney, gastrointestinal tract, or they may result from the direct extension from a malignant tumor of the lips, tongue, cheek, floor of mouth, or salivary glands.

Primary malignant tumors of the mandible include the following most common varieties: osteogenic sarcoma, chondrosarcoma, fibrosarcoma, Ewing's tumor, multiple myeloma, malignant giant cell tumor, and malignant adamantinoma. No attempt will be made to discuss these tumors as separate entities, since they behave just as they do in other bones.

All these tumors are firm to palpation and cause a dull aching pain early in their onset, followed by swelling and disturbance in mastication. They frequently metastasize early to the lungs and to other distant organs. Early and extensive destruction of bone, especially by the sarcomas, is characteristic and is readily apparent on x-ray examination of the jaw.

Treatment.—Biopsy should be done in all cases in order to establish the exact histologic diagnosis of the malignant lesion. The treatment of choice for primary malignant tumors of the mandible is radical resection of the bone with a wide margin of surrounding tissues. In Ewing's tumor and in multiple myeloma the use of radiation therapy is to be preferred. Reconstructive surgery, as a rule, should be delayed for one year to be reasonably certain that the disease has been locally controlled. The use of rib grafts, iliac crest grafts, metal and plastic bars, and molded mandibular segments have all been used to reconstruct the mandible with varying degrees of success.

Fig. 181.—Palpation of the neck. This should be done with the palmar surfaces of the tips of the fingers and should include an orderly, systematic examination.

A, Palpation of the submental and submaxillary regions.

B, Palpation of the deep cervical lymph nodes along the internal jugular vein.

C, Palpation of the posterior triangle of the neck and supraclavicular region.

THE NECK

There are numerous surgical conditions that occur in the neck. The differential diagnosis of a particular lesion will depend largely on the history and physical examination. The latter includes careful inspection and an orderly palpation of the various triangles of this region. Local inflammatory areas, visible swellings, sinuses, and fistulous tracks should all be noted.

Palpation is performed with the examiner in front of the patient. The region of the parotid salivary gland is first palpated on each side, swelling of the submandibular salivary gland, if present, is noted and the neck is then searched for enlargement of any lymph nodes. Palpation of the thyroid gland completes the examination (see Chapter 13).

THE CERVICAL FASCIA

Prior to a discussion of the surgical conditions that occur in the neck, the student

should have a thorough understanding of the anatomy of the deep fascia of the neck. The surgical importance of the fascia colli cannot be overemphasized. The cervical fascia is divided into a superficial and a deep layer. The superficial layer of the cervical fascia is thin and attenuated and lies beneath the skin, superficial to the platysma muscle. It is of no particular significance.

The Deep Cervical Fascia.—This fascia is dense and forms a definite structure which invests the principal organs, vessels, and muscles of the neck. It is divided into three layers as follows:

1 The general investing layer or the pre-visceral fascia. This layer lies deep to the platysma muscle and completely envelops all the structures in the neck deep to this muscle. It splits to enclose two muscles, the trapezius posteriorly and the sternomastoid anteriorly. It is attached superiorly to the external occipital protuberance, the superior nuchal line, the base of the mastoid process, the zygomatic

Fig. 182 - The anatomy of the deep fascia of the neck. Note the three layers of fascia and the fact that between the second and third layers there is a free passageway into the superior mediastinum indicated by the arrows in B.

Fig. 181 — Palpation of the neck. This should be done with the palmar surfaces of the tips of the fingers and should include an orderly, systematic examination

THE NECK

There are numerous surgical conditions that occur in the neck. The differential diagnosis of a particular lesion will depend largely on the history and physical examination. The latter includes careful inspection and a thorough palpation of the various triangles of this region. Local inflammatory areas, visible swellings, sinuses, and fistulous tracks should all be noted.

Palpation is performed with the examiner in front of the patient. The region of the parotid salivary gland is first palpated on each side, swelling of the submandibular salivary gland, if present, is noted and the neck is then searched for enlargement of any lymph nodes. Palpation of the thyroid gland completes the examination (see Chapter 13).

THE CERVICAL FASCIA

Prior to a discussion of the surgical conditions that occur in the neck, the student

should have a thorough understanding of the anatomy of the deep fascia of the neck. The surgical importance of the fascia colli cannot be overemphasized. The cervical fascia is divided into a superficial and a deep layer. The superficial layer of the cervical fascia is thin and attenuated and lies beneath the skin, superficial to the platysma muscle. It is of no particular significance.

The Deep Cervical Fascia.—This fascia is dense and forms a definite structure which invests the principal organs, vessels, and muscles of the neck. It is divided into three layers as follows.

1. The *general investing layer* or the *previsceral fascia*. This layer lies deep to the platysma muscle and completely envelops all the structures in the neck deep to this muscle. It splits to enclose two muscles, the trapezius posteriorly and the sternomastoid anteriorly. It is attached superiorly to the external occipital protuberance, the superior nuchal line, the base of the mastoid process, the zygomatic

Fig. 182.—The anatomy of the deep fascia of the neck. Note the three layers of fascia and the fact that between the second and third layers there is a free passageway into the superior mediastinum, indicated by the arrows in B.

arch, and the lower border of the mandible. Posteriorly it is attached to the ligamentum nuchae and to the spinous process of the 7th cervical vertebra. It is continuous anteriorly in the midline with the corresponding superficial layer of deep fascia of the opposite side. Below or inferiorly it is attached to the periosteum of the sternum, the clavicle, and the spine of the scapula, and the acromion process. Above, this fascia spreads to enclose the submaxillary and also the parotid salivary gland.

2. The middle layer of deep cervical fascia (the *pretracheal fascia* or the *viscerovascular fascia*). This fascial layer is attached to the anterior surface of the trachea. It extends upward in front of the larynx to form the pre-laryngeal fascia and ends above by being attached to the hyoid bone. It gives off a sheath anteriorly to enclose the sternohyoid, sternothyroid, and omohyoid muscles. Inferiorly it envelops the thyroid gland and extends into the mediastinum, where it ends by blending with the fibrous pericardium in the superior mediastinum. This fascia extends laterally with a process given off by the third layer of the deep cervical fascia to completely invest the carotid vessels of the neck. This is known as the carotid sheath. Further laterally, this layer continues as a fascial sheath to cover the scalene muscles and ends by merging with the fascia covering the levator scapulae and the trapezius muscles.

3. The deep layer of the cervical fascia (the *prevertebral fascia* or the *retrovisceral fascia*). This fascial layer lies in front of the vertebrae and the prevertebral muscles but behind the buccopharyngeal fascia of the posterior wall of the pharynx and esophagus. It forms the posterior layer of the carotid sheath and runs behind the pharynx, larynx, esophagus, and trachea. Above it is attached to the base of the skull, while inferiorly it extends into the posterior mediastinum where it blends with the endothoracic fascia. Laterally this layer fuses with the fascia covering the scalene muscles and ends by merging with the fascial covering of the trapezius, levator scapulae, and erector spinae muscles. This layer also splits as it extends laterally to form a dome over the apex of the pleura and lung known as Sibson's fascia. *The important point to realize here is that between the middle and*

deep layers of the deep cervical fascia, in the space containing the trachea and esophagus, there is a free passageway into the superior mediastinum.

It is possible for cervical abscesses and infections within the space to track down into the mediastinum, resulting in an acute mediastinitis with or without abscess formation.

In operations on the neck, such as tracheostomy, thyroidectomy, or radical neck dissection, this space is entered, and it becomes possible for air to be sucked down into the mediastinum. This occurs especially in those cases in which there is some obstruction to the airway; the respirations become labored and exaggerated, with an increase in the negative pressure not only in the mediastinum but also in the pleural cavities. This can result in a tension pneumomediastinum, which can lead to a rupture of the mediastinal pleura and a pneumothorax which may be unilateral or bilateral. This complication is an acute surgical emergency and must be recognized and treated as rapidly as possible.

INJURIES

Wounds of the neck are common, the majority of them being due to a suicidal attempt. However, accidental and homicidal wounds also occur. The carotid vessels are protected by the sternomastoid muscle, but deep puncture wounds may easily prove fatal due to hemorrhage. Deep wounds may reach many important structures such as nerves, blood vessels, and air passages. It is interesting that the person attempting suicide generally damages the air passages but rarely touches the contents of the carotid sheath. This is because he holds his head in the hyperextended position, very frequently before a mirror, which projects the trachea and larynx forward. The homicidal wound is more likely to cause damage to the contents of the carotid sheath. The complications of neck wounds are bleeding, infection, pneumonia, and subcutaneous emphysema. Arteriovenous fistulas can result from penetrating wounds of the neck.

Treatment.—First bleeding must be controlled. Packing the wound with gauze can control hemorrhage until the wound can be well exposed in the operating room. The

larynx or trachea may be divided or, if not, may be so badly contused that glottic edema, laryngeal or tracheal necrosis follows. An adequate airway must therefore be maintained, and this may necessitate an emergency tracheotomy.

In cases of laceration of the larynx or trachea, a tracheostomy tube can often be inserted directly through the wound. The neck wound should be débrided in the usual manner and sutured, as should also the lacerated larynx, pharynx, or trachea. A temporary tracheostomy will be necessary, because in such cases one can anticipate edema of the glottis. If the wound is grossly contaminated and there is infection, drainage should be instituted. It is wise to use antibiotics freely to prevent wound infection and also to lessen the danger of respiratory complications.

CERVICAL INFECTIONS

Boils and Carbuncles

Boils and carbuncles on the back of the neck are extremely common. Friction of collars, growth of hair, and the thickness of the skin make this area subject to infection. Here it is hard for infection to burrow to the surface, the furuncles are liable to spread as carbuncles. Boils and carbuncles here should be treated as in other locations.

Acute Infections in the Neck

They are very common and are usually secondary to infections beginning in the scalp, face, mouth, or throat. Secondary lymphadenitis ensues, and the lymph nodes may become enlarged and tender. If infection in a lymph node breaks through the node capsule, it may spread as a cellulitis, contained by the firm fascial planes in the neck. Later there may be abscess formation. It is difficult to decide when an abscess has formed, and there is no advantage in cutting into a node that is still solid. The infection is often so deep that it may be difficult to elicit fluctuation. All that one can feel is, perhaps, a firm indurated mass. By the time there is redness of the skin an abscess has usually formed. Only after a large abscess has formed does the pus break through to the subcutaneous tissues.

Treatment.—Early treatment with antibiotics will often prevent purulent degeneration of lymph nodes, especially if the local abscess in the area is controlled by incision of furuncles or extraction of an abscessed tooth. Cervical abscesses should be incised as soon as they are fluctuant.

Ludwig's Angina

Infection reaching the submaxillary triangle from the mouth, often from an alveolar abscess, may give rise to a spreading cellulitis known as Ludwig's angina. There is a firm and painful swelling in the submaxillary and

Fig. 183—Ludwig's angina which has been incised (Transverse incision gives less unsightly scar)

submental regions and in the floor of the mouth, generally with protrusion of the tongue. The inflammation may progress to such an extent as to cause edema of the glottis and death from toxemia and asphyxia. The swelling and inflammation are usually confined to this area by the investing layer of deep cervical fascia.

Treatment.—The use of antibiotics should be instituted just as soon as a diagnosis is made. The patient should be kept under careful observation, and if the edema and swell-

ing appear to be progressive, a curved transverse incision should be made in both submaxillary and submental areas even if no abscess is evacuated. The incision should extend through skin, the platysma muscle, the investing layer of deep fascia, and the geniohyoid and mylohyoid muscles in order to expose completely the submaxillary regions. The wound should be left widely open to ensure free drainage. In rare advanced cases, tracheostomy may be indicated to relieve embarrassed respiration.

Fig. 181—Recurrent tuberculous abscess of the neck.

Tuberculosis

The most frequent site of lymph node tuberculosis is in the neck. Tuberculous lymphadenitis is the most common chronic inflammation of these lymph nodes and one of the most common causes of a benign cervical tumor or swelling. Although supervision of milk supply and more rigid control of human tuberculosis have greatly reduced the incidence of cervical lymph node tuberculosis, the disease is still not rare. Early in the disease, one or several movable, discrete, rubbery lymph nodes may be palpated in any of the cervical triangles. In some cases, chains of matted nodes develop which seem to have

no tendency to undergo caseation. In most cases, as the nodes become progressively larger, they tend to caseate and become fixed to the surrounding tissues and to the skin. Late there may be secondary infection, with redness of the skin and spontaneous rupture of the abscess. Following rupture a sinus may persist. The lesions are usually painless until secondary infection appears. Fever, and loss of weight may be entirely absent. While tuberculous of the lymph nodes is generally considered to be a disease of youth, this disease is not infrequently found in those of advanced years, especially in women. X-rays may show calcification in the lymph nodes.

Treatment.—The treatment of tuberculosis has been changing during the past few years, and further changes are likely to occur. Local enlargement of a lymph node in the neck is only one manifestation of tuberculosis that exists elsewhere in the body, but this may not be necessarily so.

A diagnosis having been established, general treatment should be initiated. This includes plenty of rest, sun, and nutritious food. In recent years more or less specific anti-tuberculosis drugs have been developed, and it is not unlikely that still more efficient drugs or antibiotics will be available soon. Among the more effective antituberculosis drugs available today are streptomycin, para-aminosalicylic acid, and isonicotinylhydrazine. It appears that combined drug regimens have proved to be superior to the administration of a single antituberculosis agent in the treatment of this disease. The three best regimens investigated to date are (1) streptomycin combined with daily para-aminosalicylic acid; (2) intermittent streptomycin combined with daily isonicotinylhydrazine; and (3) a combination of daily isonicotinylhydrazine and para-aminosalicylic acid.

Of these three combinations, streptomycin and isonicotinylhydrazine appears to be the most useful. However, the other combinations of drug therapy are also effective and offer certain advantages. As a general rule, the patient should continue to receive the antituberculosis drugs until the disease reaches the inactive stage, or longer. This may sometimes take 8-12 months and, in certain cases, as long

as 18 months. Occasionally it is wise to combine drug therapy with x-ray or surgical measures. In the stage of lymph node proliferation and before caseation, x-ray therapy will often cause regression of the inflammation. In the stage of caseation and before secondary infection, local excision of degenerative lymph nodes is indicated to prevent sinus formation and to promote rapid healing. After secondary infection the abscess should generally be opened and the lymph node remnant curetted. In rare instances, one may be justified in carrying out a radical block dissection of the entire lymph node system on one side of the neck where the nodes are diffusely involved with tuberculosis and have resisted other forms of therapy. However, this should only be performed as a last desperate attempt to rid the patient of the disease.

Actinomycosis

Actinomycosis is a disease affecting man, cattle, and swine and is caused by the ray fungus, *Actinomyces bovis*, which, having lodged in the tissues, produces a granulomatous type of reaction. This reaction is characterized by inflammation, sinus formation, and the discharge of characteristic yellow sulfur-like granules. The majority of cases of human actinomycosis are found in the face and neck. The primary focus of entry is usually in the mouth, around the teeth, and in the crypts of the tonsils. The first sign of neck swelling may follow extraction of a tooth or a tonsillectomy. Abscesses soon form and break down to give rise to discharging sinuses. The fresh pus from a newly opened abscess will often contain the yellow sulfurlike granules of the actinomyces colonies. If untreated, the disease continues to burrow and produce new thick-walled abscesses and sinuses. Gradually the patient becomes thin and weak with further local spread of the disease and extension to other parts of the body, such as the liver, lungs, and brain.

Treatment.—Combined therapy of penicillin and sulfadiazine has proved most effective in many cases. It may be necessary to continue this treatment for several months. Recently the use of stilbamidine intravenously

in doses of 150 mg./day for about 12 days has shown some promise in the treatment of this disease. The use of x-ray therapy to accessible lesions has long been used with results that have been generally satisfactory. A saturated solution of potassium iodide is the traditional and sometimes the only effective means of controlling this disease. One should generally begin with an initial dose of 5 drops in water 3 times a day before meals and increase it by 5 drops daily until signs of intolerance develop, which is usually somewhere between 200 and 300 drops per day. The dosage just below that which produces symptoms is the maintenance dose and should be given for several weeks or several months, depending upon the response of the patient. Probably the most effective method of treatment is surgical. This consists of excising or curetting all diseased or dead tissue, leaving the wound open in order to provide adequate drainage. This should usually be combined with intensive doses of some form of chemotherapy as previously outlined.

TUMORS OF THE NECK

In Table 12 are listed the most common benign and malignant tumors that may be responsible for a so-called "lump in the neck." It is surprising how frequently a patient will present himself to his physician with a slowly enlarging swelling in the neck as his only complaint. It is often very difficult to decide whether the lesion is due to some chronic inflammation, benign tumor, or local or metastatic neoplasm. The commonest error in such cases is the failure of the physician to recognize the probable cancerous nature of most cervical tumors in an adult. Generally speaking, the diagnosis in a given case can be made from the following facts: a careful history which should include the age and sex of the patient, the duration of the tumor, its rate of growth, the presence or absence of pain, tenderness, or local inflammation, history of previous operations or treatment. One should then carry out a very careful physical examination of the lump, its location, consistency, size, the presence or absence of pain or tenderness, whether or not it is single, and so on.

TABLE 12
CLASSIFICATION OF BENIGN AND MALIGNANT TUMORS OF THE NECK

BENIGN TUMORS OF NECK	MALIGNANT TUMORS OF NECK
(A) <i>Inflammatory</i>	1. Metastatic cancer
1. Hyperplasia of cervical lymph node	2. Malignant lymphoma
2. Tuberculosis	(a) Lymphosarcoma
3. Actinomycosis	(b) Hodgkin's disease
4. Boeck's sarcoid	(c) Leukemia
5. Boils and carbuncles	3. Branchiogenic carcinoma
(B) <i>Congenital</i>	4. Sarcoma of soft tissues of neck
6. ThyroGLOSSAL cyst	(a) Fibrosarcoma
7. Branchiogenic cyst	(b) Liposarcoma
8. Dermoid cyst	(c) Malignant schwannoma
9. Cystic hygroma	(d) Rhabdomyosarcoma
(C) <i>Acquired</i>	5. Thyroid carcinoma
10. Carotid body tumor	6. Malignant salivary gland tumors
11. Benign thyroid adenoma	7. Parathyroid carcinoma
12. Benign submaxillary salivary gland tumors	
13. Soft part tumors	
(a) Lipoma	
(b) Fibroma	
(c) Sebaceous cyst	
(d) Schwannoma	
(e) Ganglioneuroma	
14. Parathyroid adenoma	

A careful examination of the mouth, larynx, pharynx, nasopharynx, and tonsillar region for a possible silent primary focus should be performed. One negative examination should not rule out the possibility of a primary lesion in one of those sites, since the primary growth may be so small that it is completely missed. Repeated examinations at regular intervals and by several examiners are necessary before one can be certain that this region is free of disease.

In less obvious and somewhat bizarre swellings, the diagnosis may prove to be most elusive. In such cases one should resort to complete x-ray studies of the chest, gastrointestinal tract, and kidneys. Complete blood and biochemical examinations are necessary. The blood picture may furnish information which would help to distinguish between a primary tumor and acute or chronic inflammatory swellings of the lymph nodes.

A serious and fairly common error in the management of cervical tumors or lymph node enlargements is the immediate excision or incision of a "lump" for biopsy purposes before any of the above diagnostic procedures have been carried out. Such local operative procedures diminish the prospect of cure in cases

of malignant tumors, since the resulting scarring may interfere with the subsequent treatment of this neoplasm either by surgery or with irradiation. In difficult cases aspiration biopsy of a lump in the neck is frequently successful in rendering a diagnosis of an abscess, cyst, benign tumor, or malignant neoplasm. This method is simple to perform and does not interfere with subsequent treatment of the area by whatever means prove necessary. Incisional or excisional biopsy should only be used as a last resort after other diagnostic procedures have failed.

BENIGN TUMORS OF THE NECK

Inflammatory Tumors

This group includes hyperplasia of cervical lymph nodes, pyogenic and tuberculous lymphadenitis, actinomycosis, Boeck's sarcoid, boils, and carbuncles. With the exception of Boeck's sarcoid, these have already been discussed and will therefore not be dealt with further.

Boeck's Sarcoid

Boeck's sarcoid is a chronic, indolent, benign infectious disease of unknown cause, which may involve the lymph nodes, the salivary glands, lungs, or other organs. The

systemic symptoms are usually not severe in the early stages, and they may be so mild that only skin eruption on the face or enlarged lymph nodes may be noted by the patient. When cervical lymph nodes are enlarged, they are rarely more than one inch in diameter. The nodes are discrete and elastic, they never caseate or suppurate, but they are involved in a granulomatous inflammation. Preauricular and postauricular lymph nodes are frequently enlarged. There may be a hypochromic microcytic anemia. When general lymphadenopathy and splenomegaly are present, the disease may

Fig 185—The position taken by the thyroglossal duct in its migration from the foramen cecum to the lower anterior neck. Thyroglossal cysts may occur anywhere along its course. The tract may run anterior to or through the body of the hyoid bone.

be confused with Hodgkin's disease. After a considerable time there is usually spontaneous recovery. A biopsy must be taken to settle the diagnosis. The value of all treatments is doubtful, but x-ray therapy and nitrogen mustard may have some value. Half the patients have enlarged lymph nodes.

Congenital Tumors

This group includes thyroglossal cyst and branchiogenic cyst and fistula, cystic hygroma, and dermoid cysts.

Thyroglossal Cysts and Fistulas

The embryology of this condition is discussed elsewhere. The diagnosis of thyroglossal cysts is generally simple. Most patients will present with a cystic swelling or mass in the anterior neck usually just below the level of the hyoid bone. While they tend to occur in the midline, they are not infrequently found either just to the right or to the left of the midline. Thyroglossal cysts average 3 or 4 cm but may be as large as 10 cm in diameter. They are not painful or tender unless there is secondary infection. A characteristic feature

Fig 186—Large thyroglossal cyst, characteristically situated in the midline of the neck near the hyoid bone.

of such cysts is a tendency to move upward on swallowing or on protrusion of the tongue. In about one third of the patients there is a draining sinus instead of a cyst. Such a sinus may have its opening in the anterior neck anywhere from the suprasternal notch to the region of the hyoid bone. The sinus opening results from spontaneous rupture or surgical drainage of an infected cyst.

The treatment is surgical and includes not only excision of the cyst with any external fistulous tract but also tracing and completely

Fig 187—Diagram to show the course and anatomic relations of the branchiogenic sinus tract. The internal opening is generally in the tonsillar region or, in rare instances, in the nasopharynx. A and B illustrate the lines of incision utilized when excising the tract in step-ladder fashion.

Fig 188—Branchiogenic cyst in a young adult, situated in upper lateral neck, adjacent to the anterior border of the sternomastoid muscle.

Fig 189—Infected branchial cyst with abscess formation.

resecting the thyroglossal duct to its point of origin at the base of the tongue. Since it is almost impossible to determine whether the tract runs in front of, behind, or through the substance of the hyoid bone, one must always remove the central portion of the hyoid bone as part of the dissection of the tract, otherwise recurrence may result.

Branchiogenic Cysts and Fistulas

In the embryo there are 5 branchial arches with 4 branchial grooves or clefts between them. The arches develop to form the upper and lower jaws, parts of the hyoid bone, the styloid process, part of the stapes, and most of the thyroid and cricoid cartilages. The branchial clefts and furrows form the external auditory meatus, the eustachian tube and tympanic cavity, the thymus and parathyroids. The major parts of the branchial clefts normally disappear, but they may persist in whole or in part.

The most common remnant of the branchial clefts is in the form of a branchial cyst. Branchial cysts occur with equal frequency in both sexes and usually appear in early adult life in patients 20-30 years of age. They are most frequently found in the upper third of the neck in close association with the anterior border of the sternomastoid muscle. Such cysts vary from 1-10 cm in diameter and give a history of slow steady increase in size. They generally present as smooth, movable, soft, and painless masses. Such cysts may be lined either by squamous or by stratified columnar ciliated epithelium. In those lined by squamous epithelium, the cyst contents is usually a thin, milky fluid, and if columnar epithelium is present, the cyst contents will generally be a thick, transparent, and mucoid fluid. There may be a mixture of both types of epithelium and a combination of both types of fluid. The finding of cholesterol crystals in aspirated material is diagnostic of branchial cysts.

The treatment of such cysts is excision. The use of sclerosing solutions, x-rays, repeated aspirations, or of incision and drainage is only mentioned to be condemned. An oblique incision centered over the most prominent part of the tumor is employed. The cyst should be completely enucleated, and in so

doing one must watch for possible injury to such structures as the mandibular branch of the facial nerve, the carotid vessels, the vagus nerve, the hypoglossal nerve, and the cervical sympathetic chain. The wound is drained from its inferior angle for 24-48 hours.

Branchial Fistulas.—Persistence of a branchial cleft may form a fistula on one or both sides of the neck. This condition again occurs equally often in both sexes, but unlike cysts this condition is generally seen at birth or shortly thereafter, and the majority of the cases are seen before the age of 5 years. The external opening of the fistula is usually found in the lower third of the neck and is usually in close association with the anterior border of the sternomastoid muscle just above the clavicle. Sometimes the fistula may open in the middle or even in the upper third of the neck. If an internal opening is present, it is found near the tonsillar fossa, but the tract may be incomplete. Periodic opening and closing of the fistula may be present, although most of the time, there is some discharge from the external fistula. Secondary infection and abscess formation may occur. Injection of Lipiodol into the fistula is used to show the length of the tract and to demonstrate the internal opening in the pharynx.

Treatment.—Branchial fistulas should be excised except in the very young or in the presence of active inflammation. The operation consists of excising the entire tract from the external skin opening to the entrance of the fistulous tract in the tonsillar region. When the opening is in the lower third of the neck, it may be necessary to use multiple transverse incisions in stepladder fashion, in the lateral part of the neck in order to extirpate the tract. The tract usually passes up between the internal and external carotid arteries to the wall of the pharynx. Its entrance into the pharynx is ligated with fine silk. The wound is drained for 24-48 hours.

Cystic Hygroma

This benign, congenital, multilocular cystic tumor of lymphatic origin presents in the lateral cervical region. According to Goetsch, cystic hygroma of the neck arises from sequestration of the lymphatic tissue derived from

Fig 190—Dermoid cyst of face

the primitive jugular sacs which have failed to join the lymphatic system in the normal manner. While the majority of cases occur in the neck, this lesion is also occasionally seen in the axilla, the retroperitoneal space, and the groin. The tumor is generally seen before the age of 10 years, although about 50% of the cases are noted immediately after birth. The tumor may be large and extend from the mastoid process to the clavicle, or it may be limited to a small area in the posterior triangle of the neck or in the supraclavicular region. The cysts forming the tumor are thin-walled cavities which vary greatly in size and are lined by endothelium and contain a clear watery or straw-colored fluid. The tumor has a soft irregular cystic consistency.

The treatment of cystic hygroma is primarily surgical and consists of wide surgical excision of the lesion. The use of radiation therapy and the injection of sclerosing solutions, although widely used in the past, is of limited value only.

Dermoid Cysts

True dermoid cysts are of congenital origin. They may arise from the embryonic germinal

epithelium or be produced by epithelial remnants caught in the lines of embryonic fusion. Dermoid cysts occur in a number of locations. The most common sites are the following:

1. In the midline beneath the tongue or in the floor of the mouth
2. In the midline of the neck near the hyoid bone
3. In the mid-portion of the lateral aspect of the neck, near the sternomastoid muscle
4. In the submaxillary triangle
5. In the face—most frequently found at the root of the nose, or on the forehead at the outer border of the eyebrow

The cysts vary in size from 2 to 5 or 6 cm in diameter. They are usually oval or circular in shape, rubbery in consistency, and not adherent to the skin, although they may be fixed to the underlying tissue. They are lined by stratified squamous epithelium, and sebaceous glands, sweat glands, and hair follicles may be present in the walls of the capsules. Cysts in the floor of the mouth seldom contain hair, although those elsewhere generally do. They are painless lesions and grow slowly. They can be easily mistaken for thyroglossal or branchial cysts, although if the contents of

Fig 191—Dermoid cyst of submental region which has been growing slowly for 20 years causing elevation of tongue and interference with eating

the cysts is aspirated, the diagnosis can be generally suspected. The contents of a dermoid cyst varies in consistency from thin to very thick and is composed of desquamated epithelium, sebaceous material, and hair. Dermoid cysts occasionally become infected, forming small abscesses or sinuses from which hair may protrude.

Treatment—Dermoid cysts should be removed surgically. The cyst usually shells out from the surrounding tissue quite readily unless there has been secondary infections or previous surgical interference, in which case there is dense adhesive scar tissue about it. On the scalp or face, the cyst may be attached to the underlying periosteum or even to the dura mater, and therefore removal should be carefully planned.

Acquired Cervical Tumors

This group contains such lesions as carotid body tumor, benign lipoma, sebaceous cyst, benign thyroid adenoma, benign submaxillary salivary gland tumor, schwannoma or neurilemmoma, and ganglioneuroma.

Carotid Body Tumor

Of the benign acquired cervical tumors the most important is the *carotid body tumor*. This is a relatively rare tumor that occurs in the lateral region of the neck just below the angle of the mandible and is situated beneath the sternomastoid muscle at the level of the bifurcation of the common carotid artery. These tumors can occur at any age, although they are more frequently found in middle life and occur equally often in both sexes. The carotid bodies, from which this tumor arises, are paired structures situated within the adventitia of the carotid artery near the bifurcation. The exact function of the carotid bodies is still not clear. They may be chemoreceptors which are sensitive to changes in the hydrogen ion concentration and to the carbon dioxide and oxygen tensions of the circulating blood.

These tumors generally grow slowly and in the early stages produce little or no discomfort. As they grow larger, however, they may press against adjacent organs or structures and give rise to symptoms. The tumor may grow upward toward the base of the

skull, inward toward the tonsillar region and pharynx, or outward, producing a bulge in the neck. The characteristic feature of these tumors is the fact that they can be moved in a horizontal but not in a vertical plane, due to their attachment to the carotid vessels. The tumors are occasionally bilateral. A carotid body tumor may lie either on or behind the bifurcation of the common carotid artery, or it may completely encircle the common, internal, and external carotid arteries. It always gives a transmitted pulsation and occasionally exhibits a bruit. Carotid angiography may confirm the diagnosis by findings suggestive of intrinsic defect in the carotid wall.

Treatment.—Although it was once believed that these tumors were always benign, there have been recent reports in the literature to prove that these tumors are capable of regional lymphatic spread as well as distant dissemination. Because of this fact and because if left untreated they continue to grow and cause trouble locally, removal of carotid body tumors is recommended if at all possible. The chief danger of operating upon these tumors is the fact that the carotid vessels may be completely surrounded by the growth, and in order to rid the patient completely of the tumor, it may be necessary to sacrifice the region of the bifurcation of the common carotid artery. Older patients do not as a rule tolerate this procedure, and in such people it is attended by a high morbidity (hemiplegia) and also a high mortality rate of about 45%. In recent years, however, it has been possible to re-establish the continuity of the internal carotid artery by means of nylon prostheses or venous or preserved arterial homografts. There have also been cases reported in which the distal cut end of the external carotid was successfully anastomosed to the distal end of the internal carotid artery. In such cases the blood flow is said to occur in a retrograde manner from the external carotid artery into the internal carotid artery. This tumor is radioresistant, and no regression can be expected with radiation therapy.

Primary Neurogenic Tumors

Primary nerve tumors of the neck include the following: neurofibromas, schwannomas or neurilemmomas, and ganglioneuromas.

DISEASES OF THE FACE, MOUTH, AND NECK

Fig. 192.—Lipoma of the neck.

Neurilemmomas are said to be commonest in the head and neck area. They arise most frequently from some portion of the brachial plexus in the neck and are usually seen in the supraclavicular region in the posterior triangle of the neck. They are also rarely encountered in the parapharyngeal region. In this region they arise, most usually, from the vagus or cervical sympathetic nerves. The tumor may occur at any age and the sexes are equally involved. They are usually benign and rarely do they become malignant. The tumors are usually 2-3 cm in size, but they may reach 5-6 cm in diameter. They often produce paraesthesia in the arm and hand on the affected side. Those arising in the parapharyngeal region may produce compression of the posterolateral pharyngeal wall with resultant dysphagia and sometimes hoarseness.

Ganglioneuromas arise from the ganglia of the sympathetic nerve trunk. They are more capable of becoming malignant and metastasizing than the previously discussed neurogenic tumors. The majority of ganglioneuromas are thoracic in origin and spread upward into the neck from the mediastinum. They may occur at any age and are found in both sexes.

Treatment.—The treatment of primary neurogenic tumors is surgical excision. They

do not respond to irradiation. Since most of these tumors are well encapsulated, they can be readily shelled out. One must be careful not to injure any of the nerve trunks when dissecting them from the brachial plexus or from the vagus nerve or sympathetic trunk.

Lipomas

The cervical region is the commonest site of lipomas. They are especially seen in the posterior triangle and the back of the neck. Lipomas are soft, painless tumors that grow slowly and cause few symptoms. The more superficial lipomas are usually easy to diagnose, but those that occur in the deeper tissue of the neck may feel quite firm and prove difficult to diagnose except by surgical excision.

Treatment.—Lipomas should be surgically excised both for cosmetic and diagnostic reasons. Furthermore, it is quite possible for deeper lying tumors to become malignant liposarcomas.

Sebaceous Cysts (see Face)**MALIGNANT TUMORS OF THE NECK**

Malignant tumors of the neck can be divided into two main groups:

1. Primary malignant tumors of the neck
2. Metastatic or secondary malignant tumors of the neck.

By far the most frequent type of malignant tumor in the cervical region is that due to

Fig. 193.—A, Small carcinoma of the left lobe of the thyroid gland. B, Large cervical lymph node metastasis.

metastasis in the cervical lymph nodes. The primary sites are usually in the head and neck region but may also be occasionally below the clavicle.

Primary Malignant Tumors

We have excluded from this discussion primary malignant tumors of the thyroid, parathyroid, and salivary glands because these lesions are more conveniently discussed elsewhere. This leaves for discussion the following most frequently encountered types of primary cancer of the neck:

1. Malignant lymphoma which includes all those primary malignant lesions arising in cervical lymph nodes, i. e.
 - (a) lymphosarcoma
 - (b) Hodgkin's disease
 - (c) leukemia
2. Branchiogenic carcinoma
3. Sarcoma of the soft tissues of the neck.

Malignant Lymphomas

Lymphosarcoma.—Lymphosarcoma is a progressive disease which generally begins with enlargement of a solitary lymph node in the neck. This solitary tumor may persist for some time, but eventually other nodules appear, gradually enlarge, and coalesce to form a matted chain of lymph nodes without suppuration. We include in our term lymphosarcoma the three generally recognized varieties, namely, lymphocytic, reticulum cell, and the macrofollicular types. Clinically all three types behave alike. It is almost impossible to distinguish, by clinical examination alone, lymphosarcoma of the neck from other varieties of malignant lymphoma or from metastatic cervical carcinoma. In some cases it may be possible to make a diagnosis on aspiration biopsy, but usually the pathologist will request an excisional biopsy in order to be absolutely certain of the diagnosis.

Hodgkin's Disease.—Although at one time Hodgkin's disease was considered to be an infectious process, it is now generally accepted as a form of malignant neoplasm. Again the first symptom of this disease is usually a painless swelling in the lateral part of the neck, which behaves very much like a lympho-

sarcoma. The number of lymph nodes involved in Hodgkin's disease is generally more than in lymphosarcoma, and the lymph nodes are usually firmer with more induration. As with lymphosarcoma, it is difficult to distinguish Hodgkin's disease from tuberculosis, cancer, or other forms of lymphoma. Suppuration does not appear in Hodgkin's disease. A positive diagnosis is made after biopsy of the mass. The disease is more frequent in males than in females, the course runs from months to many years but is usually fatal in 2-4 years. In the final stages there is the typical fever of Pel-Ebstein, loss of weight, and weakness. The spleen and liver may be enlarged, and x-rays of the chest may show a widening of the mediastinum due to involvement of the mediastinal lymph nodes. This type picture is variable, but anemia and leukopenia are frequently present.

Lymphatic Leukemia.—This condition is frequently associated with cervical lymph node enlargements and has the same general clinical characteristics as the lymphomas. Matting of these lymph nodes is less common than in Hodgkin's disease. Histologically, this tumor may resemble a lymphosarcoma, and for that reason a white blood count should always be made in addition to biopsy of a lymph node before a conclusive diagnosis of lymphosarcoma is made.

Treatment of Malignant Lymphoma.—Lymphosarcoma is one of the more radio-sensitive malignant tumors, and in most cases the initial response to radiation therapy will be good. In recent years there has been evidence to show that many of the cases of cervical lymphosarcoma are secondary to a single, discrete primary lesion in some portion of Waldeyer's lymphatic ring in the nasopharynx, palate, tonsil, and base of tongue. It remains localized at first and then later metastasizes to the cervical lymph nodes as does a squamous cell carcinoma. Therefore one should never treat a lymphosarcoma of the cervical lymph nodes without first carefully examining the mouth and pharynx for a possible primary focus. If present, then the primary as well as the secondaries in the neck should be treated with irradiation. In a small number of cases of lymphosarcoma in which the disease appears to have originated either

primarily in the lymph nodes of one side of the neck or to have subsequently appeared in the neck following control of a primary focus in the mouth or throat, it is permissible to attack such disease by radical neck dissection. These cases must be carefully selected, and every effort must be taken to demonstrate that there are no other areas of involvement before a radical neck dissection is performed. If there is evidence of disease anywhere else in the body, then x-ray is the treatment of choice since it indicates that the disease is no longer local but has become generalized. Postoperative x-ray therapy to the neck may be given.

Hodgkin's disease, like lymphosarcoma, is also a radiosensitive lesion. While the neck nodes are the first involved in about 60% of all cases of Hodgkin's disease, generally speaking by the time the patient presents himself for treatment, or a diagnosis is made, the disease is usually widespread. The use of nitrogen mustard and its derivatives, combined with radiation therapy, appears to be the most effective form of therapy in this group of cases. In early cases of Hodgkin's disease where the nodes involved are confined to one side of the neck with no evidence of disease elsewhere in the body, a radical neck dissection is justified, followed by postoperative x-ray therapy.

Branchiogenic Carcinoma

Branchiogenic carcinoma refers to those malignant tumors which are believed to arise in vestigial remnants of branchial pouches. This term has been applied to those cases of the malignant epithelial tumors appearing in the lateral aspects of the necks of patients in whom there is no evidence of a primary focus elsewhere in the body. In most hospitals this term is used less today because, with experience, it has been shown that the majority of such malignant tumors in the neck are metastatic from the mouth, throat, accessory sinuses, the thyroid, the major salivary glands, or even from a primary focus below the level of the clavicle. At times the primary focus is so minute that it may be completely missed on initial examination. Indeed it may not reveal itself clinically for several years. Because of this fact, the diagnosis of branchiogenic cancer should always remain tentative until the

patient has survived for five years after the treatment of the growth in the neck, without the discovery of a primary lesion elsewhere.

Treatment.—The diagnosis can be made by an aspiration biopsy or by an incisional or excisional biopsy of the mass. In those cases where the tumor is less than 3 cm in diameter, it is best to treat the lesion by means of radiation therapy. One hesitates to carry out radical surgery in these cases knowing that there is a possible hidden primary focus elsewhere in the mouth or throat which may later become obvious. When the cervical tumor is larger than 3-4 cm. in diameter, the possibility of controlling it by means of radiation therapy is much less successful, and in such cases it is perhaps more advisable to carry out a radical dissection on the affected side. Regardless of the method of treatment, the patient must be followed carefully and at frequent regular intervals in search of a possible primary lesion.

Sarcomas of the Soft Tissues of the Neck (Excluding Lymph Nodes)

Sarcomas may arise from practically any of the soft tissues of the neck, such as nerves, muscles, fascia, and vascular tissue. Such tumors may be situated along the line of the internal jugular vein and consequently may be readily confused with metastatic cervical cancer. The following types of tumors have been reported from this region: fibrosarcoma, liposarcoma, rhabdomyosarcoma, leiomyosarcoma, hemangiopericytoma, malignant schwannoma, and malignant ganglioneuroma. The diagnosis in any given case will ultimately depend upon the histologic report. Aspiration biopsy may be sufficient, but it may be necessary to make an incisional biopsy. The treatment of sarcomas, in general, is best carried out by radical surgical procedures since they are, on the whole, resistant to radiation therapy.

Metastatic or Secondary Carcinoma of the Neck

The most frequent type of cancer in the neck is that due to metastases in the cervical lymph nodes from a primary site outside the neck. It must be remembered that mere pal-

pability of cervical lymph nodes is by itself no proof of abnormality. Lymph nodes up to 2 cm. in diameter in the subdiaphragmatic area and up to 1.5 cm. in the submaxillary triangle may exist bilaterally for years in perfectly healthy people. But such bilateral symmetric, soft enlargement of lymph nodes is of little importance. It is the unilateral or asymmetric enlargement which is of more clinical significance. Cancer and tuberculosis are the commonest causes of chronic asymmetric enlargement of cervical lymph nodes, and yet, of the two, metastatic cancer is said to be about 200 times commoner than tuberculosis. Inflammatory hyperplasia of lymph nodes may also give rise to asymmetric cervical lymph node enlargement. The diagnosis in such cases is not too difficult since the nodes are generally tender and show signs of inflammation, and on careful examination one will find a focus of infection in the mouth or throat, most often in the tonsils or about the teeth. Furthermore, such lymph nodes tend to suppurate and result in abscess formation, as previously discussed. In cervical lymph node metastases, however, the lymph nodes are generally firmer in consistency. In the early cases there is a characteristic lack of pain or tenderness or any signs of acute inflammation, while finally there is a definite tendency toward steady and progressive enlargement.

The location of the cervical metastases depends on the site of the primary tumor. The first sign of a cancer of the stomach, rectum, prostate, or uterus may be the presence of a firm, enlarged lymph node above the clavicle. A metastatic lymph node in either supraclavicular area may be an indication of the inoperability of a carcinoma of the bronchus, the esophagus, or breast. An enlarged cervical lymph node may be the first obvious spread from a cancer of the testis. Martin states that the appearance of a cervical metastasis was the only symptom noted by the patient in about 85% of all cases of primary cancer occurring in organs situated above the clavicle, such as in the mouth, throat, and thyroid. When a patient with a lump in the neck presents with an ulcerating cancer of the lip, oral mucosa, tonsil, or larynx, then the diagnosis of the cervical tumor is obvious. In other instances, however, the primary growth

is not so apparent, and one must carry out a very careful examination of the base of the tongue, pharynx, extrinsic larynx, nasopharynx, and the tonsillar region. X-ray examinations of the paranasal sinuses, chest, gastrointestinal tract, and kidneys may all be required before the primary focus is finally discovered. Endoscopic examination of the larynx, the bronchial tree, and the esophagus may prove invaluable. The thyroid gland itself should not be neglected, and the presence of even the smallest nodular enlargement in any portion of the gland should be considered significant.

As the original mass in the neck grows, other lymph nodes gradually enlarge and become palpable and firm. A chain of firm nodules soon appears, and if left untreated the involved nodes eventually become matted together and fixed to the skin and surrounding tissues. Later the cancer may grow into the skin, forming an ulcer with secondary infection and foul discharge. Pain is not an early symptom but occurs later as a result of either secondary infection and ulceration or because of secondary involvement of the sensory nerves or from deep infiltration into adjacent structures. Cancers in the upper cervical areas may cause agonizing pain referred to the ear.

Treatment.—There are two main methods of treating cervical metastatic cancer, namely, radiation therapy and neck dissection. It is now generally accepted that wide removal of the cervical lymphatics offers a better chance of cure than does radiation therapy. However, the method employed in any given case will depend upon several factors, the most important being the following:

1. The location of the primary lesion and whether or not it has been controlled by previous therapy.
2. The histopathology of the malignant lesion.
3. Whether surgical treatment of the metastases will afford a reasonable chance of success.
4. Whether there is clinical or radiographic evidence of distant metastases.

Obviously, before surgery is contemplated, the primary focus, generally somewhere in the head and neck region, must be controlled. If not, it should be possible to remove it

FIG. 194.—Neck dissection completed. The operation extends from the midline of the neck to the anterior border of the trapezius muscle and from the clavicle below to the mandible above. Included in the dissection are the sternomastoid muscle, the internal jugular vein, the carotid sheath, the omohyoid muscle, the submaxillary gland and all the deep lymphatics, fatty and areolar tissue in the lateral and anterior aspects of the neck.

surgically at the same time the neck dissection is performed. Otherwise, radiation therapy offers a better chance for cure. The majority of neck metastases are secondary to squamous cell cancer of intraoral origin, and they are relatively radioresistant. However, metastatic lymphosarcoma or lymphoepithelioma, although less frequent, is generally better handled by radiation therapy because of their radiosensitivity.

Before attempting a radical neck dissection, the metastases must be clinically operable, and one must be reasonably sure of success. The main criterion of local inoperability is extension into the carotid vessels, the base of the skull, or the cervical vertebrae. In a small percentage of cases, what was originally felt to be clinically fixed and inoperable may undergo such regression after a course of radiation therapy that surgical excision becomes quite feasible. Finally one is obviously not justified in carrying out a neck dissection in cases having associated distant metastases. Here the employment of judicious amounts of radiation therapy for palliative purposes may be tried.

The term *radical neck dissection* refers to an operation that attempts to remove as completely as possible all the lymphatic tissues (lymph nodes and vessels) that are likely to be involved by metastatic cancer, together with all of the fatty and areolar tissue from the lateral and anterior aspects of the neck. The field of operation extends from the midline of the neck to the anterior border of the trapezius muscle and from the clavicle below to the mandible above. In depth it extends from the undersurface of the platysma muscle to the third layer of the deep cervical fascia. Included in the routine dissection are the sternomastoid muscle, the internal jugular vein, the carotid sheath, omohyoid muscle, the submaxillary gland, and the deep lymphatics of the neck. Any operation short of this is not complete and is generally doomed to failure. In order to afford the patient the best possible chance of cure, the first operation must be thorough and complete. The only valid reason for doing a partial neck dissection and limiting the operation to the submaxillary triangle or to the supra-omohyoid region is the fact that the patient is a poor surgical risk and not

likely to survive a radical procedure. In such cases it may be more prudent to resort to radiation therapy than to surgery.

Cervical Lymphatics

In order to appreciate the principles of carrying out a radical neck dissection one must have a thorough understanding of the anatomy of the cervical lymph channels and nodes which consist of a superficial and deep chain. The *superficial lymphatics* drain the skin and the appendages and empty into the deep cervical lymphatic chain. These lymphatics lie for the most part on the deeper aspect of the platysma muscle. They are rarely involved by metastatic cancer except from the deeper lymphatics in the very late stages of the disease, in which case large areas of skin must be sacrificed with the neck dissection. The *deep cervical lymphatics* are important because they receive lymph drainage from the mucous membrane of the mouth, pharynx, larynx, major salivary glands, and thyroid, and from the skin of the head and neck. The most important nodes in this group are those which run along the internal jugular vein from the level of the posterior belly of the digastric muscle down to its entry into the subclavian vein. These nodes vary from a few mm. to 1½ cm in diameter. The most important node in this group is the subdigastric or jugulodigastric node which is the highest node of the internal jugular chain and lies on the internal jugular vein just below the posterior belly of the digastric. It is more often involved by metastatic cancer than any other cervical lymph node. Because of the close association of the lymphatics throughout the length of the internal jugular vein, it is necessary to sacrifice this vein in order to extirpate the nodes.

The *submental lymph nodes* consist of at least a pair of nodes that lie on the surface of the mylohyoid muscles between the anterior bellies of the digastric muscles. They drain the skin of the lower lip, the chin, and the mucous membrane of the midportion of the lower lip, the anterior midportion of the floor of the mouth, and the tip of the tongue.

The *submaxillary lymph nodes* are divided into three sets: the preglandular, the intra-glandular, and the prevascular and retrovas-

DISEASES OF THE FACE, MOUTH, AND NECK

cular. They drain the mucosa of the lower lip, the cheeks, the alveolar ridge, the floor of the mouth, and the anterior two thirds of the tongue and empty into the deep cervical chain. The intraglandular lymph node which

and runs downward and backward through the posterior triangle along the course of the spinal accessory nerve. It receives the drainage mainly from the nasopharynx, but its upper end is intimately associated with the

Fig. 193.—The anatomy of the deep lymphatics of the face and neck. Note the direction of lymphatic flow.

lies within the substance of the submaxillary gland is one of the main reasons for routine removal of the latter during neck dissection. The spinal accessory chain begins beneath the upper end of the sternomastoid muscle

upper jugular chain and may receive lymphatic drainage from it. Sacrifice of the spinal accessory nerve in a radical neck dissection is necessary in order to remove this lymphatic chain completely. The transverse cervical chain

at the root of the neck connects the spinal accessory chain with the lower end of the internal jugular chain.

The *parotid lymph nodes* are arranged in two groups. The first group includes the preauricular nodes which lie superficial to the parotid sheath and drain the temporal and frontal regions of the scalp, the outer portions of the lids, and the outer ear. The second group is deep in the substance of the gland and drains the external auditory meatus, the middle ear, the nasopharynx, the soft palate, and the nose. Both groups transmit the lymph to the lymph nodes in the neck. In addition there is usually a small node lying in the lower pole of the parotid gland which may be involved first in cancer of the parotid gland and at times in cancer of the upper lip.

The *pretracheal and prelaryngeal nodes* are involved early in cancer of the thyroid gland and of the larynx. These nodes are not routinely removed in a radical neck dissection, except when one is dealing with a cancer originating in either the thyroid gland or larynx.

TRACHEOSTOMY

The term *tracheostomy* means an operative opening into the trachea maintained for an indefinite period of time, and this is in contradistinction to the term *tracheotomy* which refers to the surgical procedure of opening the trachea for temporary exploration.

Tracheostomy is a valuable and at times a lifesaving surgical procedure which has, in many instances, been neglected in the treatment of acutely ill patients. Its primary use is to maintain an adequate airway which may be difficult. The indications for tracheostomy are as follows:

1. In acute cerebral injuries and in certain cases of brain tumors and of infections of the brain, the patient may be comatose or stuporous and unable to clear his tracheobronchial tree by coughing. In such cases the aspiration of food, drink, and vomitus may present a very definite hazard, which can be more easily combated with a tracheostomy tube in place.

2. In a severe and massive injury or infection about the face and neck, there may be considerable edema of the tissues of the neck or the pharynx, causing marked respiratory embarrassment. Such patients may be further handicapped by an ineffective

cough, with real danger of aspiration of pharyngeal and other secretions.

3. In patients with severe tracheobronchitis or other similar inflammatory conditions, there may be an inadequate airway due to edema and secretions produced by the inflammatory state.

4. In all penetrating, lacerating, or severe crushing injuries to the trachea.

5. In certain surgical procedures about the head and neck such as a radical neck dissection which is combined with some intraoral procedure, such as a hemiglossectomy or a resection of a portion of the mandible. Patients undergoing a bilateral radical neck dissection in one stage in which both internal jugular veins are sacrificed should also have a prophylactic tracheostomy because of the anticipated postoperative edema.

6. Cases of benign or malignant tumors involving the larynx, pharynx, upper trachea, thyroid, tongue, and mandible which are of such a size or extension that there is compression of the upper airway.

7. In postoperative severely ill patients, in whom the cough is ineffective to clear adequately the tracheobronchial tree. In such patients repeated bronchoscopy constitutes a real risk, whereas a prophylactic tracheostomy could be easily done and prove lifesaving. Similarly in patients who are known to have advanced pulmonary disease and who undergo major surgery, a tracheostomy will usually prevent pulmonary complications.

8. Following thyroid surgery one may have to carry out an emergency tracheostomy because of hemorrhage or injury to one or both recurrent laryngeal nerves.

9. In certain individuals who have received intense irradiation for malignant tumors in the neck and who develop severe tissue reaction and edema of the upper respiratory tract.

10. In the crushed chest or stove in chest syndrome, which refers to a crushing injury characterized by multiple rib fractures and causes the movements of a portion of the thoracic wall to be paradoxical to the normal excursions of the thoracic cage. A vicious cycle results in this syndrome. First of all there is incomplete aeration of the lung because of the paradoxical movement of the chest wall. Pain is severe and, combined with the paradoxical movement, renders coughing ineffectual. Secretions accumulate in the terminal bronchioles and alveoli, thus further impairing adequate ventilation of the lung.

Tracheostomy has been shown to be of benefit in this condition in several ways. First of all, it reduces the paradoxical movement of the injured chest segment and in this way decreases pain associated with the movements of the fractured ribs. Second, it provides an easy and ready method of aspirating the tracheobronchial secretions. Third, there is a decrease in the dead space and also a decrease in resistance to the inspired and expired air.

The use of other supportive measures together with the management of any complication, must not be neglected in this condition.

Fig. 196—Tracheostomy set: 1, obturator; 2, outer tube; 3, regular inner tube; 4, inner tube with an outward extension for use in cases requiring bulky neck dressings

Fig. 197—A, Approximate location of skin incisions in relation to the thyroid gland for emergency or elective tracheostomy
B, Elective tracheostomy tube in place through the second tracheal ring

Technique of Performing ■ Tracheostomy.—Tracheostomy may be performed either ■ an emergency or as a prophylactic procedure. The *emergency tracheostomy* is generally performed ■ a heroic measure to establish an adequate airway in an individual who is choking to death. A *prophylactic tracheostomy* is one which is carried out in a patient in whom some form of respiratory complication is anticipated and in whom the insertion of a tracheostomy tube will prevent or lessen the severity of such a complication.

The procedure is relatively simple and one which can be easily performed under local anesthesia. A vertical incision is preferred since one can extend the incision up or down as required in order to get an adequate exposure of the trachea. The elective tracheostomy is always performed through the tracheal rings, preferably the first and second. The emergency tracheostomy is more easily performed through the crico-thyroid membrane as this area is relatively close to the surface of the skin and usually void of blood vessels.

The vast majority of tracheostomies are of a temporary nature, maintained during the acute phase of illness or diminished air passage. The tube may remain in situ for an indefinite period of time, but 2 to 4 or 5 days is all that is usually necessary. Under no circumstances should the tube be removed until the surgeon is positive that the upper airway is adequate without the assistance of the tube. Ordinarily the wound closes spontaneously within 2-3 days after the tube is removed.

Care of a Tracheostomy.—Bedside suction apparatus is required, and a nurse should be in constant attendance until the patient has learned to suction the trachea himself. The inner tube is removed and thoroughly cleaned inside and out twice daily. The outer tube is changed once every 2-3 days. A moist atmosphere, effected by the use of steam or a cold humidifier, is often helpful.

THE SALIVARY GLANDS

The major salivary glands consist of the paired parotid, submaxillary, and sublingual glands. These organs are liable to injuries, infections, and neoplastic processes.

Injuries

Accidental wounds or surgical operation may cause lacerations of the parotid gland or wounds of the parotid duct. A radical dissection of the cervical lymph nodes usually makes it necessary to remove the lower portion or tail of the parotid gland. In such cases and in those in which there is accidental laceration of the gland, there may be a discharge of saliva for a day or two, but with pressure dressings the wound usually heals in a few days without persistence of a salivary fistula. On the other hand, a complete transection of Stensen's duct may continue as a salivary fistula. In such cases the discharge of saliva is more copious in association with eating, and little or no parotid secretion enters the mouth through its normal channel. Pressure dressings, if instituted early, may aid in healing of the fistula. A fistula that persists after 1-2 months should be treated by operation, either to join the ends of the duct or to transplant the proximal end of the duct into the mucous membrane of the cheek. In fistulas that prove to be difficult to treat, the use of x-ray therapy will aid in reducing the secretion of saliva.

Inflammation

Aside from mumps, infections of the salivary glands are not very frequent. However, when they do occur, they may prove to be extremely painful and disabling. Two types of inflammation are recognized:

- 1 The acute suppurative infection occurring almost always in the parotid glands.

- 2 The chronic inflammation usually associated with symptoms of recurring obstruction of the ducts. In this case the submaxillary is more often affected than the parotid gland.

Acute Suppurative Parotitis.—This occurs most often in debilitated, dehydrated patients, sometimes as a postoperative complication following a serious operation, or in prolonged febrile disease such as typhoid fever, bronchopneumonia, severe tonsillitis, or pharyngitis. Old age, weight loss, chronic infection, and poor nutrition all seem to be important factors in its causation.

The organism most frequently responsible is the staphylococcus and less frequently the streptococcus which is found especially in the fulminating cases. The causative organism

travels from the mouth along the parotid duct into the gland. At times, however, it may be blood-borne.

The local symptoms are pain and swelling of one or both parotid glands, associated with fever, chills, headache, and general malaise. The mouth may be foul and dry, and pus may be expressed from the red, swollen orifice of Stensen's duct. There is usually leukocytosis, and abscess formation may occur. Since suppurative parotitis occurs in seriously ill patients, this complication may be a terminal one.

Treatment.—The prophylaxis of this condition is much more important than the treatment. The mouth should be kept clean, and dehydration must be avoided. Seriously ill and debilitated patients should be brought into an optimum condition by means of diet, blood transfusions, and correction of electrolyte imbalance before any operation is undertaken. With the advent of intravenous electrolytic solutions and antibiotics, acute parotitis has become a much less frequent postoperative complication. Chewing of gum promotes salivation and good drainage of the glands. The use of Lugol's or other mild antiseptic solution as a mouthwash is also useful.

The treatment of mild cases of acute parotitis by means of local application of heat or cold, together with intensive antibiotic therapy and oral hygiene, is usually successful. Many severe cases will also respond to this treatment. In the more resistant cases the use of x-ray therapy combined with antibiotic therapy generally succeeds. When there is frank suppuration and abscess formation, incision and drainage become imperative.

Chronic Inflammation.—As previously mentioned, this condition occurs more frequently in the submaxillary than in the parotid gland. The inflammation in this condition is generally a result of a partial or complete obstruction of the duct due to a plug of thick mucus, to swelling of the duct mucosa, or to a salivary calculus. Patients suffering from this disease may have recurrent or persistent swelling of the submaxillary gland or occasionally of the parotid gland. The pain or swelling may be especially pronounced when food is ingested. At times the exacerbations of pain and swelling of the gland are associated with

some minor inflammation such as pharyngitis. A sialogram with Lipiodol may show a narrowing stricture in Stensen's duct, or there may be a partial or complete blockage of the duct by one or more stones, or there may be dilatation of the smaller ducts and acini in the gland with puddling of the Lipiodol, the result of chronic inflammation.

Treatment.—Oral hygiene must be maintained. The actual treatment will vary with the type of obstruction. Simple probing of the duct may succeed in re-establishing the flow of saliva. If the meatus of the duct is constricted, it is incised for a distance of $\frac{1}{2}$ -1 cm. with suture of its epithelial lining to the mucosa of the cheek. If the obstruction is due to a stone in the duct, the calculus should be removed. In those cases where there are multiple stones within the gland substance itself or where there is evidence of chronic inflammation by a sialogram, a partial or complete removal of the salivary gland is indicated.

Mikulicz's Disease.—Until recently this disease has been a rather vague and ill-understood entity. It has been referred to by a variety of terms, chronic inflammation, lymphoepithelioma of Fein, lymphocytic tumor, adenolymphoma; more recently Godwin has suggested the term *benign lymphoepithelial lesion* as describing best its clinical course and histologic characteristics. In the original disease as described by Mikulicz in 1888, both lacrimal glands and all the salivary glands were diffusely involved in a tumefaction. From his description of the clinical and histologic features of the disease, the appearance is very similar to those subsequently described under the headings mentioned above. It is unnecessary for the lacrimal glands to be involved for a diagnosis of Mikulicz's disease. The lesion may present unilaterally in the parotid gland, or bilaterally or successively in both glands, and may or may not involve the other major salivary glands. As a general rule their involvement is extremely rare.

The true nature of this lesion is unknown. Although most likely an inflammatory process, there are some instances, however, which present features suggestive of a neoplasm. Histologically, the lesions consist of a mass of lymphoid tissue containing scattered foci of

epithelial cells that are traceable to ductal origin. The disease may be in scattered foci with involvement of the entire gland, or it may be localized to a single nonencapsulated focus, or it may be circumscribed and encapsulated.

The prognosis of this lesion is excellent, and none of the cases reported have run a malignant course. The patients respond well to surgical or irradiation therapy. If the diagnosis can be established without operation, x-ray therapy is perhaps more satisfactory. With a localized lesion where the diagnosis is uncertain, resection of the tumor may have to be carried out.

Fig 198—Calculus in Wharton's duct, causing swelling of the submaxillary salivary gland. This lesion must be distinguished from a neoplasm which may present an identical clinical appearance.

Salivary Calculi—Salivary stones occur more frequently in the submaxillary salivary gland or duct than in the parotid gland or duct. As previously mentioned, calculi may cause recurrent inflammation and swelling in a salivary gland, aggravated by eating. Stones vary in size from a few mm up to 2 cm. or more in diameter and are frequently multiple, especially when small. Their exact mechanism of formation is not clearly understood, but they probably result from a precipitation of salts upon desquamated cells in stagnant salivary secretion. Ninety per cent of the stone is composed of calcium carbonate and calcium phosphate, while the remainder is made up of cellular debris, cholesterol, and other organic material.

Clinically the patient complains of an intermittent, swollen, and perhaps painful mass in the vicinity of the submaxillary gland or less frequently of the parotid gland. The pain is usually aggravated when food is taken. On examination the calculus may be felt somewhere along the course of the duct by combined intraoral and extraoral palpation. Inspection will disclose some redness or swelling about the orifice of the duct from which pus may be expressed. X-ray of the gland or duct will demonstrate the calculus.

Treatment—A stone in Wharton's duct may be removed by an incision in the floor of the mouth. A stone in Stensen's duct is removed by exposing the duct through an incision in

Fig 199—X-ray and photograph of salivary calculi.

the buccal mucosa, feeling for the stone, and removing it by an incision into the lumen of the duct directly over the stone. If the calculus is in the submaxillary gland, it is better to excise the gland through an incision in the submaxillary triangle. Similarly, troublesome stone or stones in the parotid gland are best treated by a partial parotidectomy.

Tumors

The parotid salivary glands account for approximately 87% of all such tumors, the submaxillary glands for about 12%, and the sublingual glands for less than 1%. In addition to arising from the major salivary glands, salivary gland tumors may arise from the minor salivary glands situated within the oral mucosa or in the upper respiratory tree, so that these tumors may appear in the tongue, hard or soft

palate, buccal mucosa, floor of mouth, trachea, or bronchus. The present discussion will be confined to tumors of the major salivary glands.

By far the most frequent type of tumor is the so-called benign mixed tumor. However, it is estimated that approximately 30% of parotid tumors are malignant, and one must keep this possibility in mind when dealing with any parotid tumor.

Our knowledge of the classification and behavior of salivary gland tumors is still incomplete. The pathologist continues to describe new histologic entities which as yet have not been completely correlated with specific clinical findings. In Table 13 is compiled a classification of benign and mixed salivary gland tumors with their relative incidence.

Clinical Features.—Tumors arising in the major salivary glands are found in patients of all ages. Benign salivary gland tumors are commoner in the 5th decade, while malignant tumors are more frequent in the 6th and 7th decades. The sex ratio between patients is almost equal, although malignant tumors are more frequently found in males.

In the case of the parotid gland approximately 50% of the tumors are situated in the tail or inferior portion of the gland, that is, that part below and slightly anterior to the lobule of the ear. The next most frequent site is in the anterior or mid-portion of the gland, accounting for approximately 25%. Thus the majority of parotid tumors are found in the so-called superficial portion of the gland, which is that part of the gland super-

ficial to the facial nerve and its main branches. At times the growth may arise in the deep or retromandibular portion of the gland. Since extension laterally is blocked by the ascending ramus of the mandible, the tumor tends to grow medially and may present as a bulge in the pharynx or tonsillar region.

In over 80% of the patients the only initial symptom of a benign salivary gland tumor is the presence of a slow-growing lump in the parotid or submandibular region. This mass is typically freely movable and painless and may have been present for months or even years before medical advice is sought. There is no fixation to the skin or to the surrounding gland substance. In a smaller percentage of patients, there is some degree of local discomfort associated with the tumor. In the case of malignant salivary tumors pain may be an early and quite prominent symptom. The rate of growth is slow, but it may suddenly become more rapid, at which time one must suspect a malignant lesion.

Benign mixed tumors are so called because of the varied microscopic picture which they present. At one time it was believed they were composed of a number of elements, fibrous and mucous tissue, cartilage, epithelial and endothelial cells. It is fairly well accepted today that these tumors arise from the epithelium of the salivary gland. There is definite evidence to show that a benign mixed tumor is capable of becoming malignant. At times this change takes place suddenly without previous operative interference, while at other times the change occurs only after multiple operations over a period of many years.

In the diagnosis of tumors of the salivary gland one must differentiate chronic inflammation, hypertrophy of the preauricular lymph nodes, sebaceous cyst, lipoma, branchiogenic cyst, metastatic cervical cancer, and a calculus in the submaxillary or parotid salivary ducts or glands.

Malignant tumors in their early stages may differ in no way from simple mixed tumors. Their rate of growth at first, like that of a mixed tumor, may be quite slow. However, they usually undergo a period of sudden or

effective method of treatment is surgical. However, radiation therapy does play a very useful role, particularly in inoperable or recurrent lesions. Even the surgical management of salivary gland tumors (especially parotid) is not as good as it might be as judged by the average recurrence rate of 30-35% of benign mixed tumors reported in medical literature.

In this group of tumors there are a number of reasons for failure of initial therapy:

1. Lack of adequate knowledge of the surgical anatomy of this region. The constant fear of injury to the facial nerve prevents the surgeon from carrying out an adequate and complete operation.

2. The tendency of many surgeons to simply enucleate the tumors. This principle of treating salivary gland tumors is wrong. It has been

Fig 200—Benign mixed tumor of the parotid salivary gland. Note that the most prominent portion of the tumor lies below the lobule of the ear.

rapid increase in size. The tumors are generally quite firm and in the more advanced stages may become fixed. Facial nerve paralysis, when associated with a persistent swelling in the parotid region, is almost always diagnostic of a malignant salivary gland tumor. Metastases to the regional lymph nodes occur in approximately 30-50% of the patients, depending upon the histologic type of cancer. Distant metastases to lungs, bones, liver, and brain are not infrequent.

Treatment.—In general, salivary gland tumors are not radiosensitive, and the most

Fig 201—Benign mixed tumor arising from the minor salivary glands in the buccal mucosa.

shown on repeated occasions that the capsule itself is often incomplete and that microscopic tumor cells extend into and even beyond the capsule into the adjacent parotid tissue.

3. Attempts are made to remove a tumor without adequate preparation or assistance. This can happen when a doctor attempts to remove in his office or in the clinic a pea-sized nodule in the parotid region with the mistaken impression that it is a sebaceous cyst or lymph node. He generally finds himself dealing with a larger or more deeply seated parotid tumor with ultimate spillage of tumor cells through-

out the operative field or injury to the facial nerve or both

In our opinion, the best exposure for the excision of a parotid tumor is a Y incision, two arms of which run up in front of and in back of the lobule of the ear, third arm extending downward and forward into the upper neck. The first principle of the operative removal of any parotid tumor is to secure complete exposure of the parotid gland and tumor by wide reflexion of the skin flaps. It is imperative that one avoid injury to the 7th cranial nerve. The best way to prevent such an accident is to first expose the main trunk of the nerve as it emerges from the stylomastoid foramen and then to proceed to dissect out its various branches within the substance of the parotid gland. Since most of the tumors are situated in the superficial portion of the parotid gland, one should carry out, in the majority of cases, a superficial parotidectomy. In smaller tumors it may be justifiable to remove the tumor alone, together with a rim of normal-appearing parotid tissue around it. There have been many other methods advocated in the literature for identifying the facial nerve. In most of these, one or more of the peripheral branches of the nerve on the face or in the upper neck are isolated and then traced back through the substance of the gland to the main trunk of the nerve. This method is much more difficult and is fraught with real danger of injuring one or more of these small peripheral branches.

In cases of cancer and in cases where one is dealing with a benign mixed tumor arising in the deep portion of the gland, it is necessary to carry out a total parotidectomy. In a benign tumor, every effort should be made to spare the facial nerve and its branches. However, when dealing with cancer, especially when the growth lies adjacent to or infiltrates the nerve or its branches, then one should not hesitate to sacrifice those branches or even the entire nerve in order to remain wide of cancer.

In cancer of the parotid gland where there is clinical evidence of metastatic cervical lymph nodes, a radical neck dissection should be carried out as part of the primary surgical treatment of the cancer. In those cases in which there is no clinical evidence of cervical

lymph node metastases, one must be guided by the type of tumor in question and its relative malignancy.

In benign submaxillary salivary gland tumors, one generally carries out a complete dissection of the contents of the submaxillary triangle through a curved incision situated approximately two fingerbreadths below and parallel to the lower margin of the mandible. The lymphatics as well as the submaxillary salivary gland are completely removed *en bloc*. In a malignant submaxillary gland tumor, one should also carry out a radical neck dissection, whether or not the other deep cervical lymph nodes are involved. Since the neck must be entered surgically, it is easier to complete the entire operation at this time than to wait for clinical evidence of metastases to appear later, at a time when previous scarring will have made the neck dissection much more difficult.

Complications of Treatment.—

Recurrence of Tumor.—The postoperative recurrence rate of benign mixed tumors of the parotid gland reported in the literature averages around 30%. It is our opinion that the majority of recurrences is due to faulty technique, such as the enucleation of a tumor, the spillage of tumor cells in the wound inadvertent or otherwise, and failure to resect in a sufficiently wide or radical manner. Reports from the Lahey Clinic by Marshall and Force and from the Memorial Hospital by Fixsell show a recurrence rate for the primary benign mixed tumor of 6.4% and 4.8%, respectively, when the tumor has been treated in the manner described above.

The recurrence of malignant tumors following surgery is a serious complication, since it is generally associated with further spread of the disease and the ultimate death of the patient.

Facial Nerve Palsy.—Disregarding those cases in which one deliberately sacrifices one or more branches of the facial nerve because of involvement by tumor, one still sees an incidence of approximately 12-15% of facial nerve paralysis which varies from a minor degree of weakness about the mouth to total paralysis of the side of the face. The cause of the paresis is generally due to the trauma caused by excess handling or stimulation of the nerve. In the majority of cases one can

assure the patient of eventual and complete recovery.

Frey Syndrome.—This is also referred to as the auriculotemporal syndrome and is characterized by sweating and flushing of the cheek over the cutaneous distribution of the auriculotemporal nerve. The exact etiology of this phenomenon is not too clear.

Salivary Fistula.—This is a rare complication following subtotal parotidectomy. One may occasionally encounter a small accumulation of saliva under the skin where pressure dressings were not adequately maintained to permit adherence of the skin flaps to the underlying tissue. This soon subsides.

Loss of Sensation About the Ear.—This condition is due to damage or section of the great auricular nerve and is rarely permanent.

Chapter 13

Surgery of the Endocrine Glands

Stewart Baxter, MD, Chauncey J Partee, MD, James F Hopkirk, MD,
and John T. MacLean, MD

The title of this chapter is somewhat misleading since surgery of the endocrine glands is not a completely separate surgical specialty. The endocrine glands are so widely scattered anatomically that they normally fall into the province of the regional specialist. Thus pituitary conditions are dealt with by the neurosurgeon, the adrenal lesions by the urologist or abdominal surgeon, and so on.

However, for the convenience of the reader, the surgery of the endocrine glands has been incorporated into one chapter. The physiology of the organs discussed has been presented in some detail, since this knowledge is necessary for an understanding of the surgical problems involved. The careful preoperative, operative, and postoperative handling of these patients depends on this knowledge and is essential for the successful outcome of operative procedures.

THE PITUITARY GLAND

Anatomy

The human pituitary gland consists of a *pars anterior*, separated from a *pars posterior*, or neural lobe, by cystic spaces lined by epithelial cells which make up the *pars intermedia*. The *pars posterior* is connected by the infundibulum with the median eminence of the tuber cinereum in the floor of the third ventricle. The *infundibulum* is a stalk which is invested by a vascular epithelial cuff, the *pars tuberalis*.

The gland lies in a bony fossa, the sella turcica, within the body of the sphenoid bone.

The floor is bone, immediately below which lies the sphenoid sinus. The roof is formed by a dural membrane which is continuous with the dura covering the floor of the skull. It is perforated by a foramen through which passes the infundibulum. The anterior wall of the sella turcica terminates in the tuberculum sellae, on either side are seen the anterior clinoid processes. Posteriorly it is bounded by a plate of bone, the dorsum sellae, from which project the posterior clinoid processes.

Cytology.—The pituitary gland arises from both epithelial and neural tissue. The cells in the anterior lobe are arranged in closely packed columns or irregular masses, separated by vascular sinuses lying in a connective tissue stroma. There are three main types readily divided by their staining reaction—*chromophobe*, the cytoplasm of which does not stain, and the *chromophil* which is subdivided into acidophil and basophil according to the staining reaction of the granules. The posterior lobe and infundibulum are composed of a network of nonmyelinated nerve fibers and supporting neuroglial cells called *pituitocytes*; these latter may contain melanin-like pigment granules. Basophil cells similar to those found in the anterior lobe are commonly found in the posterior lobe.

Blood Supply.—Blood is supplied to the anterior lobe by a number of hypophyseal arteries which arise from the internal carotid and posterior communicating arteries. Most of these enter the *pars tuberalis* and thence course

to the anterior lobe; others enter the body of the gland directly. The inferior hypophyseal arteries arise from the internal carotid arteries in the cavernous sinuses and enter the posterior lobe. The venous blood return is not well established. The afferent or portal vessels run down the pars tuberalis, and an efferent or systemic vessel drains the gland from its lateral walls. The hypophyseal portal veins arise from a plexus of wide capillaries which lie on the surface of the infundibulum between it and the pars tuberalis. The systemic veins arise from the sinusoids of the anterior lobe.

Nerve Supply.—A considerable number of nonmyelinated nerve fibers arise from the cavernous sympathetic plexus and run in the connective tissue capsule of the gland. Many of these pass into the gland in the anterior and lateral walls. A few of these ramify among the epithelial cells. Two other large groups of fibers enter the gland with the hypophyseal arteries.

The posterior lobe is connected with the hypothalamus by thousands of nonmyelinated nerve fibers—many are connected to both the paraventricular and the supraoptic nuclei.

Physiology

The number of anterior pituitary hormones is uncertain. Ultimately the exact number will be determined when they are all obtained in pure form. The hormones are proteins or proteinlike substances and the establishment of biologic purity is difficult and sometimes apparently an impossible task. The measures used to obtain biologic purity include electrophoresis, ultracentrifugation, and solubility analysis.

Six anterior pituitary hormones have been obtained as relatively homogeneous proteins. These have been localized as follows: luteinizing hormone, ICSH, growth hormone, and prolactin in the acidophilic granules and follicle-stimulating hormone, corticotropin, and thyrotropin in the basophilic granules.

Adrenocorticotrophic Hormone.—Potent preparations of corticotropin isolated from bovine, sheep, and whale pituitaries manifest similar physiologic effects in animals and in man.

No significant increase in adrenal weight is observed in the first few hours after initiation

of stress or injection of corticotropin. Continuous exposure to stress or continuous administration of corticotropin induces adrenal hypertrophy. The increase in weight is proportional to the dose. The adrenal cortex is depleted of ascorbic acid, cholesterol, and the sudanophilic material. The increase in urinary steroids and eosinopenia are only rough guides of corticotropin activity. A mixture of steroids is elaborated from the adrenal cortex on being stimulated by corticotropin. In the dog, at least three biologically active steroids have been isolated from adrenal vein blood: 17-hydroxycorticosterone (hydrocortisone compound), corticosterone (compound B), and a potent sodium-retaining factor (aldosterone).

Corticotropin is rapidly inactivated in the organism. It is not excreted in the urine in a biologically active form. It is absorbed readily from intramuscular and subcutaneous sites and is effective by intravenous injection. It is inactive by the oral route.

This hormone is used therapeutically either intramuscularly every 4 hours, one injection of the long-acting substance every 24 hours, or by intravenous infusion.

Growth Hormone.—A purified hormone has been obtained from bovine and porcine pituitaries. This hormone normally accelerates growth in the young organism. The increase in body weight is characterized by the deposition of a tissue high in protein and low in fat. Optimal growth can only occur when the tissues of the organism have adequate quantities of thyroid and adrenal cortical hormones. Animals treated with the growth hormone utilize elements of the diet more efficiently. There is a marked stimulation of the epiphyseal cartilages.

Nitrogen is retained in association with a gain in body weight, but it is felt that the full potentialities of protein synthesis are evident only when insulin is present in appropriate quantities. Purified hormone is said to produce both a hypoglycemia and a ketonemia in animals as well as to reduce greatly the glomerular filtration rate and tubular secretory activity of the kidneys.

Evidence has been presented that a substance is present in the blood of patients suffering from gigantism, which induces an increase of epiphyseal growth in hypophy-

sectomized rats. However, the present purified preparations of growth hormone only occasionally have a protein anabolic effect in man. This presents a frustrating problem and perhaps will only be answered by further purification of this substance.

Thyrotropin (TSH)—Highly potent preparations have been obtained from beef and sheep pituitaries. Administration to the normal animal results in an increase in the weight of the thyroid. Hyperplasia is induced while there is loss of colloid and an increase in acinar cell height. The rate of accumulation of I^{131} in the thyroid is increased. The conversion of iodides to thyroxine is increased as indicated by the rise in plasma protein-bound iodine, following administration of TSH. The identity of TSH with the exophthalmic factor has not been established. This hormone is effective by the parenteral but not by the oral route.

Gonadotropin (FSH and LH)—Isolation of pure FSH from sheep pituitary has been claimed recently. LH as a chemically homogeneous protein has been isolated as a preparation from hogs and sheep. The ovary responds to the gonadotropins with growth of the primordial follicle, ovulation and corpus luteum formation. Steroid hormones which affect growth and development of the endometrium and other sex organs are liberated from the ovary under stimulation of the gonadotropins. The corpus luteum is maintained by prolactin or luteotropin (ICSH). In the male rat, FSH initiates and stimulates spermatogenesis, while LH stimulates Leydig cells which secrete the androgenic steroid. FSH and LH are inactivated rapidly by the proteolytic enzymes of the gastrointestinal tract and have no effect if administered orally.

Prolactin—This protein has been extracted from hog, beef, and sheep pituitaries. Riddle named the substance prolactin which at that time stimulated the crop sac of pigeons and induced lactation in mammals. Although it has been established that extracts of the anterior pituitary maintain lactation in various animals, the exact nature of the galactopoietic agent is uncertain. It is felt that prolactin is confined to lactogenesis. This hormone has been claimed to be luteotropic, final evidence has not been presented in man that this is so. This hormone is ineffective when administered orally.

Anterior Pituitary Endocrinopathies

A variety of endocrinopathies are produced by either hyperfunction or hypofunction of the anterior pituitary. The commonest cause of such endocrinopathies is intrasellar or extrasellar tumors.

Gigantism and Acromegaly.—These diseases can be ascribed to an excessive secretion of growth hormone. The time of onset determines whether gigantism or acromegaly will develop. When the onset follows epiphyseal closure, acromegaly results.

Briefly the outstanding features are as follows:

In *gigantism*, there is excessive height with fairly normal body proportions and increased length and thickening of the bones.

In *acromegaly*, the skin is thickened and thrown into folds. The tongue, lips, nose, and ears enlarge; and there are prognathism and enlargement of malar and supraorbital ridges, kyphosis and enlargement of the hands and feet, and visceromegaly and thickening of bones.

Common to both are adrenocortical hypertrophy, thyroid hypertrophy, and gonadal atrophy or hypertrophy. Serum inorganic phosphorus is increased, glucose tolerance is often impaired, and there is insulin resistance. The BMR is increased in some patients. Hypertension and diabetes mellitus are commoner in the acromegalic. Such disturbances are accounted for by an increase in growth hormone and a possible increase in TSH, ACTH, and gonadotropins.

Cushing's Disease.—The underlying pathology in this disease is that of a basophilic adenoma of the anterior pituitary gland. This tumor results in an excessive secretion of corticotropin (ACTH). Almost all features of the disease have been reproduced by the administration of ACTH or cortisone. Briefly the outstanding features are as follows: Acne, hirsutism, striae, easy bruisability, thinning of skin, moonface, buffalo hump, thinning of arms and legs, muscular weakness, depression of libido, and amenorrhea. Hypertension is present which may or may not be accompanied by renal disease. Polycythemia, lymphocytopenia, and eosinopenia are found. The glucose tolerance curve is impaired and there is insulin resistance. The plasma sodium and

A.

B.

Fig 203 -A, Patient with Cushing's disease. The pituitary tumor was excised, showing mixed carcinoma.

B Typical abdominal striae, same case.

chloride are normal or slightly elevated, while the potassium is low. The patient is in a negative nitrogen balance, due undoubtedly to an increase in the output of compound F or "S" hormone and a relative decrease in androgenic substances or "N" hormone. Thus also accounts for the osteoporosis so commonly found.

Adrenocortical hypertrophy and gonadal atrophy are present.

Hypopituitarism.—The disturbances of this disease are due to deficiencies of all tropic hormones of the anterior pituitary. Such deficiencies may be caused by post-partum necrosis (Sheehan's syndrome) and by pressure from an adjoining tumor (chromophobic, eosinophilic, basophilic, craniopharyngioma, or extrasellar). Irradiation may have the same effect. Simmonds originally described the condition of pituitary cachexia. Such patients are rarely seen now, chiefly because the condition is diagnosed at an earlier stage, prior to the development of extreme cachexia.

Essentially the disturbances seen in panhypopituitarism are due to the inability of the target organs, the thyroid, adrenal, and gonads, to function due to the fact that they are not being stimulated. The clinical picture presented represents a combination of the signs and symptoms of underfunction of all three endocrine glands. Hypofunction of these glands need not be complete. The most common form of hypopituitarism seen is that of partial hypopituitarism. The cause is most commonly that of partial destruction due to an expanding chromophobe adenoma. When such a tumor is present, the gonadotropic hormone is the first one of the pituitary hormones to be deficient. This results in amenorrhea or impotence, a point well to remember when amenorrhea is the presenting symptom.

Craniopharyngiomas have been mentioned previously as a cause of hypopituitarism. This is referred to as Frohlich's disease. In this condition, as originally described by Frohlich, the hypophyseal duct cyst or craniopharyngioma produced hypothalamic as well as pituitary destruction, with obesity, retarded growth, hypogonadism, and diabetes insipidus being present. It is assumed that the obesity and diabetes insipidus were present because of hypothalamic damage as neither the TSH nor

ACTH is shown to be deficient. This condition represents a form of partial hypopituitarism.

Diagnostic Techniques.—

1. **Fundi examination:** Papilledema is not often present, but careful examination of the fundi is necessary.

2. **Visual fields:** These should be determined. Various degrees and combinations of field defect can occur, depending upon the pattern of infringement of the optic nerves or chiasm. A bitemporal hemianopsia is the most common finding.

3. **X-ray sella turcica—stereolateral views** are recommended. Erosion of the clinoid processes or the floor may be present.

4. **Ventriculogram:** This procedure may be helpful or necessary when it is suspected that the tumor responsible for the hypopituitarism is extrasellar.

Treatment.—Treatment of pituitary syndromes represented by acromegaly, gigantism, or Cushing's disease will not be discussed in detail. Once the diagnosis is established there are three types of treatment. (1) medical, (2) x-ray, or (3) surgical.

Medical.—The administration of stilbestrol or a natural estrogen has been shown by Albright to depress pituitary function. Stilbestrol 3-5 mg. per day is usually adequate. This is most useful in women.

Irradiation.—Eosinophilic adenomas are radiosensitive in approximately 50% of instances. The effect, however, is likely to be transient.

Basophilic adenomas are radiosensitive in only a small percentage of cases.

Chromophobe adenomas are not amenable to medical treatment, as the chromophobe cell is nonfunctioning. They are radiosensitive in approximately 65% of instances.

The effect of x-ray treatment to the pituitary is not manifest for 3-6 months after cessation of treatment. If the patient has symptoms or signs of hypopituitarism prior to treatment, further hypofunction may ensue. Adrenal crisis must be kept in mind. Supportive therapy with cortisone during this period is sometimes helpful. The course of x-ray usually takes 3-6 weeks—4,000-4,500 roentgen units are delivered over bitemporal portals.

SURGERY OF THE ENDOCRINE GLANDS

Craniopharyngioma is a cyst and is not radiosensitive; therefore surgery is indicated if the cyst is expanding.

Surgical—Removal of a pituitary tumor is indicated whenever the lesion has expanded sufficiently or persistently to produce progressive loss of vision or severe headaches. There is no difficulty with the former indication; the latter creates considerable controversy. To state that headaches are definitely secondary to an expanding lesion, in the absence of eye signs, is not always easy.

Prior to surgery it is essential to know what, if any, supportive therapy is necessary. The main concern is to determine the degree of function of the adrenal gland. It is well for the surgeon to remember that hypopituitarism always develops after surgery. Should likely that the patient will survive the stress of the operation. Some centers administer cortisone routinely prior to the removal of a pituitary adenoma. If time does not allow for adequate preoperative evaluation, 25 mg. of cortisone is administered orally q.6h., beginning two days preoperatively. On the morning of operation 100 mg. of cortisone is given intramuscularly. This is repeated in eight hours' time. When the patient is able to swallow, cortisone may be given orally in 25 mg doses q.6h., or 100 mg of Hydrocortone may be given intravenously at the time of operation, if there is a drop in blood pressure. Cortisone is slowly discontinued over the next week, eliminating 12.5 mg each day.

THE THYROID GLAND

Embryology

The major portion of the thyroid gland originates from the pharyngeal endoderm at

the level of the first pouch. It soon develops into a solid mass attached to its point of origin by a narrow stalk—the thyroglossal duct. About the fifth week this stalk disappears, leaving a small depression at the base of the tongue, known as the foramen cecum. The remainder of the stalk is often found as a fibrous cord, but in some individuals remnants of epithelium lead to the formation of thyroglossal cysts and sinuses. The mass now assumes its position with a lobe on each side of the trachea and in the seventh week fuses with the rudimentary fifth pouches, which are ultimately transformed into thyroid tissue. The primitive mass now undergoes transformation into acini and follicles containing colloid material.

Anatomy

In the adult, the thyroid gland, consisting of a right and a left lobe, joined by the isthmus, lies on the anterior surface of the larynx and trachea at the level of the 5th, 6th, and 7th cervical vertebrae. A third, or pyramidal lobe, often extends from the isthmus or medial aspect of either lateral lobe to the level of the hyoid bone. The average weight of the gland is 30-50 Gm.

The arterial supply comes from:

- 1 The superior thyroid artery, a branch of the external carotid
- 2 The inferior thyroid artery, a branch of the thyrocervical trunk of the subclavian
- 3 The thyroidea ima artery which arises from the innominate artery or arch of the aorta. The veins form a plexus from which emerge the superior and middle thyroid veins, which empty into the internal jugular vein. The inferior thyroid vein joins the innominate vein.

STAGES IN THE FORMATION OF THYROXIN

The gland is covered by a loose external capsule, a part of the deep cervical fascia, and an internal one bound to the gland forming the interlobular septa. The parenchyma is composed of groups of acini or follicles lined by low cuboidal epithelium. The acini are normally filled with iodine containing colloid, which after fixation stains deeply with eosin. The important relations of the thyroid gland are the larynx and trachea which it partly surrounds, the carotid sheath, laterally; the esophagus posteriorly to the trachea, the recurrent laryngeal nerve, and the parathyroid bodies.

which is released into the circulation under control of the thyroid-stimulating hormone of the anterior part of the pituitary gland.

Recently the presence of free iodinated amino acids such as triiodothyronine has been identified in thyroid tissue, and it is suggested that these free amino acids play an important part in thyroid function.

The control of hyperthyroidism by iodine is thought to be due to the following:

- 1 Inactivation of thyrotropin
- 2 Interference with the action of thyrotropin on the thyroid

Fig. 204—Palpation of the thyroid gland. This examination can be made with the examiner standing behind or in front of the patient.

A, Palpation of the thyroid gland from behind the patient. The patient is asked to swallow, and as the gland moves between the fingers, each lobe can be carefully assessed and compared for size and consistency.

B, With the examiner standing in front of the patient, the larynx is displaced by the examiner's thumb, first on one side and then to the other. The dislocated lobe can now be accurately palpated between the fingers and the thumb of the opposite hand.

Physiology

The thyroid is an important ductless gland, regulated by the thyrotropic hormone of the anterior lobe of the pituitary gland. The formation of its internal secretion, *thyroxin*, is complex and as yet not completely understood. Ingested iodine must first be converted into sodium iodide and then, by an oxidase reaction, united with tyrosine to form diiodotyrosine. A second oxidation reaction links two molecules of diiodotyrosine to form thyroxin,

- 3 Prevention of the release of thyroxin, causing its retention in the gland.

Antithyroid drugs are believed to block an essential oxidation step in the formation of thyroxin, preventing the union of tyrosine with iodine.

There are two main functions of thyroxin.

1. To regulate body metabolism
2. To stimulate physical and mental growth

An overactive gland in adults produces a clinical state of hyperthyroidism or Graves'

disease, whereas an underactive gland results in myxedema. In children, an underactive gland is associated with a state of cretinism—dwarfed stature, underdeveloped secondary sex characteristics, and marked mental retardation. The hypoaactive state can be controlled by the administration of thyroxin, the active hormone of the gland, or thyroid extract. Cholesterol metabolism is also influenced by the thyroid gland. Thus in hyperthyroidism, the blood cholesterol is reduced and in myxedema, elevated.

CONGENITAL ANOMALIES

Lingual Thyroid

This anomaly represents the persistence of a part or all of the thyroid gland at its point of origin at the base of the tongue or the foramen cecum. It is present from birth but tends to enlarge at puberty, during pregnancy, and at the menopause. Symptoms are due to the presence of a swelling at the base of the tongue, difficulty in speaking, swallowing, or breathing, and a desire to swallow continuously. Bleeding may result from trauma and ulceration. The tumor is single, in the midline, and occurs predominantly in females. The treatment consists of surgical removal, provided that there is thyroid tissue in the normal site; otherwise total myxedema will result.

Thyroglossal Cysts and Sinuses

Signs and Symptoms.—These anomalies may occur at any site along the course of the thyroglossal duct. They are most common below the hyoid bone but may be found at any level from the foramen cecum to the sternal notch. They present in the midline as a firm, round swelling averaging 1-2 cm in diameter. They are attached to the deep structures, particularly the hyoid bone, but not to the skin unless infection has occurred. If a sinus is present, it is also in the midline and frequently results from incision and drainage of an infected cyst. It exudes clear or purulent mucoid material. If the sinus connects with the foramen cecum, clear saliva exudes.

The differential diagnosis includes submental lymphadenitis, dermoid or sebaceous cyst, ec-

topic thyroid or pyramidal lobe enlargement, and tuberculous fistula.

The treatment is surgical removal of the cyst and tract following it to the foramen cecum, by division of the hyoid bone, if necessary. Injection of the cyst or tract with methylene blue prior to the dissection aids in tracing the sinus tract to its highest level. Unless completely removed, recurrence is inevitable. As in lingual thyroid, proof of the existence of a normal thyroid prior to excision of a cyst is essential (See also Chapter 12.)

INFLAMMATORY DISORDERS

Acute and Subacute Thyroiditis

Thyroiditis is a disease of unknown etiology. It may occur in a subacute form or as an acute suppurative process which goes on to a localized abscess requiring incision and drainage. The subacute form is the more frequent. The disease affects females twice as frequently as males and occurs chiefly in the 20-50-year age group. Upper respiratory infections are frequently a predisposing cause.

Signs and Symptoms.—There is usually a sudden onset of swelling and tenderness of one lobe of the thyroid gland, although the entire gland may be affected. Migration from one lobe to the other is common. There may or may not be fever, chills, cough, and dysphagia. The affected part of the gland is hard, tender, and the superficial tissues are frequently reddened and edematous if the process is situated anteriorly. The basal metabolic rate is not elevated, and there are no eye signs of hyperthyroidism. Most cases run a self-limiting course of several weeks or months if untreated or if localization and suppuration do not supervene.

The differential diagnosis includes hemorrhage into a degenerating colloid nodule, carcinoma, and phlegmon of the neck. In protracted and doubtful cases biopsy is indicated.

Various specific treatments have been advocated. Antibiotics do not affect the subacute type. X-ray therapy has brought about resolution of the process in many cases. The use of antithyroid drugs such as propylthiou-

racil over weeks has also produced the same result. Recently *cortisone* has been found to influence the fibrotic pathologic process and return the gland to normal. If a localized abscess occurs, it should be incised and drained.

Pathologically, there is evidence of a diffuse subacute inflammatory process. Leukocytic infiltration and giant cells are noted.

Chronic Thyroiditis

Two distinct forms of a chronic thyroiditis, struma lymphomatosa (Hashimoto's disease) and Riedel's struma (woody thyroiditis), are recognized

Struma Lymphomatosa.—This is a chronic degenerative disease of the thyroid gland in which there are varying degrees of lymphoid and fibrous tissue replacement. It is not regarded as the end result of subacute thyroiditis, nor is it associated with Riedel's struma. The etiology is unknown. It occurs chiefly in women in the 30-40-year age group.

Signs and Symptoms.—Firm symmetric or finely nodular enlargement of the gland is the chief symptom. It may be present for years. There are no associated toxic or febrile symptoms. Many cases show a moderate degree of hypothyroidism and occasionally myxedema. Large tumors encircling the trachea cause symptoms of compression. There is no tendency toward spontaneous remission.

The *diagnosis* is usually only made at operation, and cancer of the thyroid may be suspected. Recently Crile has advocated biopsy with the Silverman needle and mild doses of x-ray therapy.

Treatment.—Thyroidectomy is usually performed on the larger types. Conservative resection is advised, since subtotal or total resection leads to severe myxedema. Enough gland is removed from the isthmus and lobes to relieve pressure on the trachea.

The *pathologic picture* is characterized by extensive degeneration of the thyroid acini and replacement by lymphoid and fibrous tissue. Well-developed germinal centers are present. There is no extension to the capsule or surrounding tissues.

Riedel's Struma.—Riedel's thyroiditis is a chronic inflammatory fibrosing process involv-

ing one or both lobes of the thyroid as well as the surrounding capsule, muscles, trachea, and blood vessels. It produces a hard bulky tumor which may be indistinguishable from advanced cancer. It is a distinct clinical and pathologic entity of which the etiology is unknown.

Signs and Symptoms.—The onset is slow, insidious, and not accompanied by pain or tenderness. Pressure symptoms are common, due to distortion or compression of the trachea. There is little systemic reaction, and the metabolic rate is normal except in advanced bilateral cases, when it is subnormal. The tumor is stony hard and fixed, leading to the presumptive diagnosis of cancer.

Treatment.—X-ray has no effect on this type of thyroiditis. Surgical removal is difficult due to fibrosis extending outside the gland. Enough gland should be removed to relieve pressure symptoms. Recurrence in the remaining lobe in unilateral cases has been reported. Radical removal is usually impossible, and the danger of injury to recurrent nerves, vessels, and parathyroid glands is increased.

Specific Thyroiditis.—Tuberculosis and syphilis of the thyroid gland are practically unknown.

TUMORS OF THE THYROID GLAND

This classification for descriptive purposes is divided into (1) nonmalignant and (2) malignant tumors.

Nonmalignant Tumors

By far the most common tumor of the thyroid gland is described loosely by the term *goiter*; other benign histoid tumors of the thyroid gland, such as fibroma, chondroma, myxoma, are so rare that no further elaboration is necessary.

Goiter, as a term applied to various types of enlargement of the thyroid gland, has been classified in various ways, none of which is entirely satisfactory. That adopted by the American Society for the Study of Goiter follows:

(A) Diffuse goiter

- (1) Without hyperthyroidism
- (2) With hyperthyroidism

(B) Nodular goiter

- (1) Without hyperthyroidism
- (2) With hyperthyroidism

In this classification diffuse goiter with hyperthyroidism corresponds to Graves' disease and nodular goiter with hyperthyroidism to "toxic adenoma."

Diffuse and nodular goiters without hyperthyroidism represent the various manifestations of endemic or colloid goiter. In addition, Crile uses the term "discrete adenoma" to describe a clinical entity when there is an adenoma which from the clinical standpoint has the qualities of neoplasia rather than of an involuntary colloid nodule. This concept has some bearing on the higher incidence of carcinoma in single as opposed to multinodular goiters.

Diffuse Goiter Without Hyperthyroidism

This corresponds to the simple adolescent colloid goiter—endemic goiter of iodine-deficient areas. It appears usually during puberty or pregnancy when the physiologic demands on the gland are greatest. With recurring episodes of iodine deficiency, the gland begins to react irregularly, and the multinodular involutionary type of goiter develops. This is the end result of many adolescent colloid goiters and accounts for the large nodular glands seen in older women in goitrous areas.

The treatment of adolescent goiter lies chiefly in its prevention, since once hyperthyroidism is established it never completely regresses, and this type of goiter progresses over a period of years to multinodular goiter and its complications. The universal use of iodized salt, the addition of small amounts of iodine (e. g., 1 m. Lugol's solution once a week, in early cases, will help to prevent subsequent enlargement.

Nodular Goiter Without Hyperthyroidism

This type of goiter results from previous adolescent enlargement and is the end result of endemic goiter. The complications of this type are (1) pressure symptoms from excessive growth—dyspnea, dysphagia, and hoarseness; (2) hyperthyroidism, (3) intrathoracic growth, (4) development of malignancy (5-10%).

The treatment of multinodular goiter is somewhat controversial. In the early stages, surgery may not be indicated. However, when any of the above complications are present, as well as for cosmetic reasons, thyroidectomy should be performed.

The Single Discrete Adenoma

Recently the existence of a discrete firm nodule in the thyroid gland has come to be regarded as a different and more serious problem, quite separate from that of multinodular goiter. The discrete adenoma has clinical and pathologic possibilities that make its removal advisable regardless of size or other constitutional symptoms, for it is this type of nodule that shows the highest incidence of malignancy (20%).

Diffuse Goiter With Hyperthyroidism (Graves' Disease)

The exact etiology of toxic goiter is not definitely known. Certain theories have been formed. It is thought by many that overactivity of the thyroid gland is brought about by excessive stimulation by the thyrotropic hormone of the anterior pituitary. The varying degrees of exophthalmus, when present, are regarded as due to this same source.

The use of tracer doses of radioactive iodine and the radioautograph of the gland have demonstrated important facts. By this method it has been shown that in many cases of solitary toxic adenoma, the adenoma is solely responsible for the toxicity, the remaining thyroid tissue being inactive.

Severe mental strain, anxiety, shock, and acute illnesses have been regarded as predisposing factors. It has also been observed that people with inherent psychotic personalities are likely to develop hyperthyroidism. Females are affected 3-4 times as often as males. The 20-50-year age group includes the majority of cases.

The signs and symptoms of hyperthyroidism are produced chiefly by the increased metabolic rate and increased oxygen consumption of the tissues. The objective signs are characteristic at first, but the symptoms have considerable variations and in the absence of objective signs are not reliable in diagnosis.

Nervousness, tremor, sweating, and excessive appetite are common symptoms. The objective signs include tachycardia, capillary pulse, high pulse pressure, loss of weight, diffuse enlargement of the thyroid gland, and various eye signs. Palpable enlargement of the gland and exophthalmus are not always present. Diarrhea and a negative calcium balance, resulting in skeletal decalcification, may be found in severe cases. Amenorrhea also occurs. Weakness of various groups of skeletal muscles may be a feature in some cases, especially the quadriceps group. Atrophy of the shoulder

Fig. 207.—Photograph of patient with exophthalmic goiter, showing exophthalmus and typical facies

girdle muscles is not uncommon. Carbohydrate metabolism is disturbed due to impaired glycogen storage in the liver, leading to glycosuria and elevated glucose tolerance curves, during the digestive phase.

Diagnosis.—Symptomatically, hyperthyroidism may be confused with anxiety states or neuroses, and in older individuals cardiac symptoms such as fibrillation or early decompensation may obscure the picture. The following tests are available as diagnostic aids.

1. **The Basal Metabolic Rate.** This is the oldest and most widely used test but is open to certain mechanical and personal inaccuracies. Bed rest, sedation, and repeated tests may be necessary to obtain the true level.
2. **Serum Cholesterol.** The serum cholesterol is lowered in most cases of hyperthyroidism, but this test is of limited value since the normal range is so wide (150-250 mg. %). This test is particularly useful when a change in original cholesterol value is noted with treatment.
3. **Estimation of Protein-Bound Iodine.** This test measures the amount of circulating thyroid hormone. It is considered by some to be the most valuable test, but due to technical difficulties it is not readily available.
4. **Therapeutic Tests.** The response to therapeutic treatment with iodine or an antithyroid drug can be used to determine the presence of mild hyperthyroid states. The objective signs such as slowing of the pulse rate, lowering of the blood pressure, weight gain, and reduction of basal metabolic rate, etc., will be noted following administration of the drug if thyrotoxicosis is present. The therapeutic test should not be continued longer than 2-4 weeks, after which time definitive treatment must be planned.
5. **Radioactive Iodine (I^{131}).** The estimation of the percentage uptake of a tracer dose (50 microcuries) of I^{131} by the thyroid tissue is a valuable method of diagnosis. The patient must not have taken any thyroid medication or preparation used for cholecystograms, pyelograms, bronchograms or myelograms for several weeks or months prior to the test. Correlation with the clinical picture and other thyroid tests is essential, since there is a considerable variation in the uptake of normal individuals (15-40%). This test is also required prior to the administration of a therapeutic dose of I^{131} .

Treatment.—The treatment of hyperthyroidism has in recent years become more complicated. For many years the standard procedure was preoperative preparation with iodine and thyroidectomy. While this is a satisfactory procedure in many cases, the degree of improvement prior to operation was minimal in severely toxic debilitated patients or in those with cardiac complications. The discovery of the antithyroid drugs propylthiouracil and Tapazole brought about a new era in the treatment of toxic goiter. With these drugs it is now possible to reduce a high metabolic rate to normal and keep it there for indefinite periods of time so that the patient comes to operation in the best possible physical condition.

In certain cases, the prolonged use of these drugs may bring about a permanent remission (40-60%).

Recently the use of radioactive iodine has opened a new method of controlling and curing hyperthyroidism

CHOICE OF TREATMENT—The decision as to the best form of treatment in cases of diffuse or nodular hyperthyroidism is based on a careful clinical, metabolic, and social investigation of the individual case. While thyroidectomy after adequate preparation is still the treatment of choice in patients who are young and good surgical risks, there are definite indications for the other forms of treatment now available.

INDICATIONS FOR DEFINITIVE MEDICAL TREATMENT WITH ANTITHYROID DRUGS—

1. Recurrent hyperthyroidism following thyroidectomy

2. Older age groups or those with some physical debility contraindicating surgery

3. Certain patients who elect medical therapy. Propylthiouracil 100-200 mg every 8 hours is given until the metabolic rate falls to normal or slightly subnormal. The dosage can then be reduced until the maintenance dose is found. Treatment usually must be continued for 12-14 months, at which time the drug is gradually withdrawn. Permanent remissions vary between 40-60%. In moderately and severely toxic patients, with enlarged glands, the recurrence rate after discontinuing antithyroid drugs is high and this type of case does better with thyroidectomy.

INDICATIONS FOR USE OF RADIOACTIVE IODINE—The use of radioactive iodine has increased in recent years with the greater availability of radioactive isotopes. Encouraging results are reported from various centers. The drug is given in water, either one estimated total dose or multiple small doses of 5-10 millicuries at intervals. The incidence of myxedema seems to be higher with the single-dose technique. The multiple-dose method requires about 6 months to secure control of hyperthyroidism. The possibility of late effects of gamma radiation on the thyroid gland is not yet fully known. Whether radioactive isotopes have carcinogenic and genetic effects is still

controversial. Some centers restrict their use to the following groups:

1. Those patients who are 45 years of age and over

2. Recurrent cases that are poor surgical risks

3. Patients who refuse surgery and do not respond to antithyroid drug treatment

Thyroidectomy.—

PREOPERATIVE TREATMENT.—In preparation for operation, the patient is given propylthiouracil, 100-200 mg. every 3 hours until an euthyroid state is reached. Lugol's solution 5-10 ml three times a day is next added for 7-10 days to reduce the vascularity and friability of the gland. Subtotal thyroidectomy is then performed. During the administration of iodine or antithyroid drugs, careful attention must be given to other aspects of hyperthyroidism. Adequate rest or bed rest with bathroom privileges is required. A high, caloric, high vitamin diet is essential to restore lost weight. Extra carbohydrates are necessary to replace glycogen depletion of the liver. Sedation, bromides, and barbiturates are useful in controlling nervous manifestations. Patients with incipient decompensation or auricular fibrillation should be digitalized prior to operation.

ANESTHESIA—The early technique of local infiltration and cervical block has largely disappeared in favor of newer anesthetic agents. The administration of a basal anesthetic such as Pentothal or Avertin in the patient's room, followed by intubation and endotracheal nitrous oxide or cyclopropane anesthesia, is the ideal combination. It assures an unobstructed airway at all times and reduces the total amount of anesthetic agent required.

TECHNIQUE—The technique of thyroidectomy is now well standardized and emphasizes the following points: (1) a well-controlled properly prepared patient; (2) anatomic dissection of the gland; (3) exposure and protection of the recurrent laryngeal nerves; (4) preservation of the parathyroid glands; (5) resection of the optimum amount of gland to effect a cure but not to produce myxedema; (6) careful hemostasis and good cosmetic closure of the incision.

A low collar incision is placed 1-1½" above the sternal notch. The superior thyroid artery

Fig 208—Technique of the stages of thyroidectomy

is then isolated, clamped, and doubly ligated with silk or heavy catgut, care being exercised not to injure the superior laryngeal nerve

The middle thyroid and inferior thyroid veins are now divided and ligated, and the gland is rotated medially to expose the posterior capsule. The inferior thyroid artery is identified and ligated well away from the capsule. The parathyroid glands may occasionally be identified close to the entrance of the branches of the inferior thyroid artery into the gland. Careful dissection in the region of the branches of the inferior thyroid artery exposes the recurrent laryngeal nerve as it approaches the gland and reduces the incidence of nerve damage. The gland is now divided across the isthmus, and the lobe is resected from the midline outward, leaving the posterior capsule intact over the recurrent nerve and the parathyroid bodies. The amount of tissue left is largely an individual factor. Usually it represents only a thin layer of tissue in the tracheo-esophageal angle and on the posterior capsule. The isthmus and pyramidal lobe, if present, should be removed. The opposite lobe is similarly resected, careful hemostasis is secured; drains are placed to either thyroid bed emerging behind the sternomastoid muscles in the line of incision. The cervical fascia and thyroid muscles are sutured, and the skin is approximated carefully with clips.

COMPLICATIONS —

A. Early —

1 *Postoperative shock* is prevented by the use of adequate amounts of glucose solution and blood or plasma if indicated.

2 *Postoperative hemorrhage* Postoperative bleeding will occur occasionally even after careful attention to hemostasis. If a large enough clot develops, it will eventually cause sufficient pressure on the trachea and larynx to produce dyspnea and stridor. If these symptoms are not relieved, the patient will die from asphyxia. Inspection of the wound and, if bulging and tense, removal of clips and opening of deep cervical fascia may be a lifesaving procedure. Later evacuation of the clot and ligation of the bleeding point can be done in the operating room. If the laryngeal compression has been present for some hours before release, a temporary tracheostomy may be required to pro-

vide an adequate airway since edema and swelling of the true and false cords may be marked enough to obstruct respiration.

3. *Recurrent nerve injury.* Partial or complete injury to one recurrent laryngeal nerve does not, as a rule, give any serious respiratory embarrassment. There will be difficulty in expectoration of mucus. The voice will be hoarse but ultimately will return more or less to normal. Section of both nerves produces complete obstruction of the airway since both cords fall into the cadaveric position. Serious dyspnea, cyanosis, and stridor develop soon after operation and require lifesaving tracheostomy.

4. *Tetany* results from removal of parathyroid bodies and may be temporary or permanent. It usually manifests itself about the third or fourth postoperative day with numbness and tingling, carpopedal spasm, and positive Chvostek's sign. The administration of calcium gluconate intravenously will relieve any alarming symptoms. The blood calcium is usually below 8 mg %. The majority of cases are transitory and yield to symptomatic treatment. Permanent tetany requires the use of A. T. 10 (dihydrotachysterol) and increased calcium ingestion.

5 *Thyroid crisis* This is an increase in all the preoperative symptoms, tachycardia, hyperthermia, extreme restlessness, delirium, and coma, which may appear during the first 24-48 hours postoperatively. It occurs rarely and less frequently since the use of the anti-thyroid drugs. The treatment consists in heavy sedation, morphine 15-30 mg or even sodium Pentothal intravenously, and copious intravenous fluids, 3,000-5,000 ml of 5% glucose solution daily. Lugol's solution 20-60 m may be added to the intravenous fluid once or twice a day. The hyperthermia is controlled by ice water or alcohol sponges, or the patient may be literally packed in ice. Death in delirium and coma rarely results.

II Late —

1 *Recurrent hyperthyroidism* as distinguished from continuing hyperthyroidism occurs in about 2% of thyroidectomies for toxic goiter. Years may elapse before the recurrence.

2 *Myxedema* or *hypothyroidism* is seen in temporary or permanent form in 3-5% of

thyroidectomies. It yields readily to the administration of thyroid extract and does not constitute a disability.

3. *Malignant exophthalmos*, a progression of the exophthalmos found in diffuse toxic goiter, occurs in a small number of cases even when the hyperthyroidism has been controlled by medication or operation. It is thought to be due to a continuation of stimulation by the thyrotropic factor of the anterior pituitary. In extreme cases marked proptosis, edema of the cornea, sclera, and eyelids, diplopia, corneal ulceration, and ophthalmitis may occur. Gradually increasing doses of thyroid extract 0.12-0.48 Gm. a day over long periods of time have produced clinical improvement. Large doses of estrogens and pituitary irradiation have also been used with varying success.

Orbital decompression by removal of the roof of the orbit and periorbital fat is indicated in severe cases. Osteoplastic recession of the eyeball (Naffziger) has been necessary to avoid the possibility of an enucleation of the eye.

Nodular Goiter With Hyperthyroidism

Hyperthyroidism associated with nodular goiter occurs most often in older age groups from 40-60 years. There is little difference in the signs and symptoms from those of Graves' disease. There is a higher incidence of cardiac complications, auricular fibrillation, and early decompensation, due partly to the advanced age group and partly to the chronicity of many of these cases. The toxicity may be undiagnosed until cardiac symptoms supervene. The same principles apply to the management of this type of goiter as those laid down for diffuse toxic goiter. It is usually unwise to attempt definitive medical treatment with antithyroid drugs, and thyroidectomy after suitable preparation is indicated.

Malignant Tumors of the Thyroid Gland

Carcinoma of the thyroid gland is the most common form of malignant tumor encountered, but rare cases of sarcoma have been reported. Metastatic involvement of the thyroid gland is also very rare.

Carcinoma of the Thyroid Gland

The etiology of cancer of the thyroid is unknown. The presence of a pre-existing nodule has been reported in as high as 50% of cases. Diffuse hyperplasia rarely results in carcinoma.

The antithyroid drugs are carcinogenic in animals in large doses, and reports of carcinoma developing in patients with toxic goiter who are receiving prolonged thiouracil therapy have been recorded.

Cancer of the thyroid is more common in goitrous districts, affects females 3-4 times as frequently as males, and occurs most often in the 40-70-year age group.

Classification.—The various types of cancer of the thyroid differ markedly in their degree of malignancy and hence their prognosis.

A classification on this basis is the most satisfactory.

- I. Tumors of low-grade malignancy
 - (a) Papillary cystadenoma
 - (b) Hurthle's cell tumor
- II Tumors of moderate malignancy
 - (a) Papillary adenocarcinoma
- III. Tumors of high-grade malignancy
 - (a) Adenocarcinoma
 - (b) Giant cell carcinoma
 - (c) Spindle cell carcinoma

The earliest symptom is the presence of a nodule in the thyroid gland which suddenly and progressively enlarges and becomes firmer than the surrounding gland. Nodularity and calcification may be noted. The appearance of dyspnea, dysphagia, pain, voice changes, loss of weight, and fixation of the mass to surrounding structures are all late manifestations and represent usually an inoperable or incurable stage of the disease. About 15-20% of cases may show varying degrees of toxicity.

The clinical diagnosis of carcinoma of the thyroid is a dubious one and, if obvious, usually represents an inoperable stage. The diagnosis is unsuspected in about 40-50% of cases of surgically removed nodules and is only made on careful pathologic study; 10% of surgically removed nodular goiters and 25% of solitary nodular goiters have been reported carcinomatous. Careful scrutiny of all nodular goiters and exploration of all suspicious cases, especially the solitary nodules, are clearly indicated. The scanning of nodules following the

use of a tracer dose of I^{131} is a useful procedure. The finding of a so-called "cold" nodule may indicate a carcinoma.

The treatment is radical thyroidectomy, but the technique is dictated by the individual case and the type of lesion suspected. In those cases where a subtotal thyroidectomy has been performed and the diagnosis made only on histologic examination, if the focus is small and completely removed, the prognosis is good. Postoperative x-ray therapy gives added protection. In the papillary type of carcinoma, if glandular metastases are present, a careful dissection of the region involved is performed. X-ray therapy postoperatively is usually indicated.

In treating the more malignant types of carcinoma, ligation and resection of the internal jugular vein well above the limits of the gland are performed before removal of the thyroid lobe on the affected side is undertaken. Similarly, the inferior thyroid veins are ligated early. This is done to prevent blood stream contamination during operation. The strap muscles and recurrent laryngeal nerve are sacrificed if involved by the tumor. Postoperative radiation is essential. Bilateral involvement by carcinoma is rarely operable. Frankly inoperable cases may be temporarily improved by heavy roentgentherapy usually combined with tracheostomy.

Radioactive iodine has been used in the treatment of carcinoma of the thyroid. Unfortunately most carcinomas of the thyroid are nontoxic and do not take up radioactive iodine in sufficient quantity to be of any therapeutic value.

The rare cases with toxicity have been successfully controlled with large doses of radioactive iodine over a long period of time (250 millicuries over a 3-year period). The use of tracer doses and estimation of the uptake by the involved gland or metastatic lesions indicate the possibility of treatment by this method.

The use of antithyroid drugs has been found to increase the absorption of radioactive iodine in certain cases.

Total thyroidectomy has been performed and causes an increased uptake of radioactive iodine by the metastatic lesions.

Radioactive iodine has not proved to be of significant value for the treatment of carcinoma of the thyroid gland.

THE PARATHYROID GLANDS

Surgery of the parathyroid glands involves chiefly the treatment of hyperparathyroidism, which is caused by an adenomatous enlargement of one of the glands.

Embryology

The parathyroid glands first appear as thickenings of the third and fourth pharyngeal pouches in the 10 mm embryo. Those arising from the third pouch remain attached to the thymic body, descend with it, and eventually lie on the posterior surfaces of the inferior poles of the thyroid. The other two glands remain in their original positions and are related to the posterior surfaces of the superior poles of the thyroid gland. This mode of origin accounts for the variability in the number and position of the parathyroid glands.

Physiology

The function of the parathyroid glands is to regulate calcium metabolism, through their internal secretion, *parathormone*, which was isolated by Collip in 1925. Surgical removal of the parathyroids leads to a state of tetany. Overactivity of the parathyroids due to hyperplasia or adenoma results in the clinical syndrome of hyperparathyroidism. The parathyroid hormone produces first an excess secretion of phosphorus in the urine, leading to hypophosphatemia. Then due to the solubility relationship with calcium, hypercalcemia develops, accompanied by hypercalcinuria.

When the serum phosphorus is lowered the serum calcium is raised and vice versa. Thus in hyperparathyroidism the alteration of phosphorus metabolism creates a demand for calcium which is derived first from the gastrointestinal tract or, failing this, from the bones.

There is some evidence that the parathyroid hormone may have a slight direct action on bone itself.

Primary Hyperparathyroidism

This disease was known for many years as von Recklinghausen's disease of bone or

SURGERY OF THE ENDOCRINE GLANDS

osteitis fibrosa cystica until 1925 when Mandl demonstrated the exact relationship between the clinical syndrome and parathyroid adenoma.

Etiology.—The cause of this condition is the great majority of cases is due to adenoma of a parathyroid gland, but in occasional instances there is hyperplasia of all parathyroid glands. The symptomatology is the same in either case. It occurs most commonly in the 20- to 40-year age group.

Signs and symptoms may be divided into three separate groups

1. Those due to *increased blood calcium*. The blood calcium is always elevated, 12-18 mg % and the blood phosphorus reduced below normal (1-2 mg %). This results in lassitude, hypotonia, weakness, constipation, anorexia, and loss of energy.
2. *Skeletal involvement*. The excessive mobilization of calcium from the bones results in marked skeletal decalcification as evidenced by x-ray. Spontaneous fractures are common. Bone cysts and tumors which may be single, but are usually multiple, are found on x-ray survey of the skeletal system.
3. *Symptoms of renal involvement*. Due to excessive urinary excretion of calcium and phosphorus, calculi, or calcinosis of the renal parenchyma, may occur. Signs of renal colic and renal infection are common.

The *diagnosis* may be difficult due to the variability of the signs and symptoms and simulation of other diseases. However, since the clinical entity has become better known, early diagnosis is less difficult. The x-ray and blood pictures are characteristic and usually diagnostic. The performance of a calcium balance study indicates that the patient is markedly negative balance. The patient is placed on a measured calcium intake (120 mg daily) and the excretion in the urine estimated. If the urinary excretion is above 200 mg/24 hours, hyperparathyroidism is suspected.

Rarely the tumor may be palpable in the neck, or there may be forward displacement of the lateral thyroid lobe.

The *treatment* of hyperparathyroidism is exploration of the posterior surface of the thy-

roid gland and removal of the adenoma or resection of two or three glands if hyperplasia is found. Considerable difficulty may be encountered if the adenoma is situated anomalously; cases requiring three, four, and five operations are reported.

The most common site for adenomas is at either lower pole (35% each), but they may be found in the carotid sheath, behind the esophagus, and in the superior mediastinum.

Careful anatomic dissection must be maintained until the tumor is found. Frozen section of suspicious nodules removed at operation is a great aid in finding the adenoma, since the histologic picture is quite characteristic.

Complications.—Injury to recurrent laryngeal nerves is best avoided by careful dissection and identification of these structures early in the operation.

Postoperative tetany due to a sudden drop in blood calcium levels must be anticipated. Frequent determination of the blood calcium during the first postoperative days and by use of calcium gluconate intravenously and by mouth will usually control the hypocalcemia until the remaining glands stabilize the blood level.

A. T. 10 (dihydroxycholesterol) also aids in maintaining normal blood calcium levels over long periods of time.

Results.—Complete recalcification of the skeletal system occurs in about a year following removal of a parathyroid adenoma.

Secondary Hyperparathyroidism

This results from an overcompensating mechanism in conditions where there is a disturbance of the calcium-phosphorus metabolism. This disturbance is a tendency to low serum calcium found in pregnancy, lactation, rickets, osteomalacia, and renal osteitis fibrosa generalisata. This type of hyperparathyroidism usually responds to medical measures, and operation is rarely necessary.

THE ADRENAL GLAND

The cortex and the medulla are discussed separately because of the distinct difference in their physiologic activity and pathologic states.

THE ADRENAL CORTEX

Anatomy

The adrenal glands are situated extraperitoneally, above and in front of the upper poles of the kidneys and on either side of the spine. The left gland is usually larger than the right one. The average weight of a gland is from 3-4 Gm. They are surrounded by a considerable amount of fat and connective tissue. Each gland is divided into the cortex and the medulla.

The cortex is deep yellow in color and contains three distinct layers.

The *external zone* (zona glomerulosa) is relatively small in the adult and consists of

cortex the columns of cells are surrounded by a capillary network, while in the zona reticularis there are sinusoids formed between the cell groups. These sinuslike spaces then drain into sinusoids present in the medulla which open into veins that merge and leave the gland as the adrenal vein. On the right side this drains into the inferior vena cava, on the left into the renal vein.

The lymphatics run in the capsule and drain into the lumbar glands.

The nerve supply is derived from the celiac and renal plexuses, which in turn receive cholinergic fibers from T₅-L₁ via the splanchnic nerves.

Fig. 209—Venous drainage of the three paired glands, and lymphatic drainage of the adrenals

small cells forming groups indicating an alveolar structure.

The *middle zone* (zona fasciculata) makes up the bulk of the cortex. Large polygonal cells run in regular rows between which are sinusoids.

The *inner zone* (zona reticularis) consists of small cells with dark nuclei, probably the remnant of the fetal zone which did not undergo involution.

The blood supply is rich and derived from branches of the aorta and the inferior phrenic and renal arteries. In the outer part of the

Physiology

Twenty-eight crystalline steroids have been isolated from the adrenal cortex and their structures identified chemically. Of these 28 steroids, seven have been shown to have physiologic activity. They are corticosterone (cpd B), 17-hydroxycorticosterone (cpd F), 11-dehydrocorticosterone (cpd A), 17-hydroxy-11-dehydrocorticosterone (cortisone) (cpd E), 11-desoxycorticosterone (DCA), and 11-desoxy-17-hydroxycorticosterone (cpd S). Aldosterone has recently been isolated. Following extraction of the known active principles,

the amorphous fraction is left. Many investigators feel that a wealth of material remains to be discovered in the amorphous substance

Chemical formula for cortisone

It is convenient to think of panels of activity in discussing adrenal cortical function.

Carbohydrate panel 17-hydroxycorticosteroids are probably the most active of the 11 oxygenated adrenal steroids in causing liver glycogen deposition. This glycogen is derived from an increased catabolism of protein. The action of the hormone or hormones is at the level of the whole protein or the inhibition of synthesis of protein from amino acids. Gluconeogenesis is the term used for this breakdown of protein to carbohydrate.

This activity is measured in the blood by the Porter-Silber technique or by the Nelson-Samuels modification. Free 17-hydroxycorticoids or possibly conjugates are extracted. Normal values range from 7-15 gamma %.

The total urinary 17-hydroxycorticoids measured by the Porter-Silber method includes both biologically active, essentially free material and mostly inactive conjugates. Normal values range from 3-9 mg/24 hours.

Electrolyte panel. The influence on electrolyte metabolism is on the renal tubular function as well as the distribution of electrolytes in the intracellular and extracellular compartments. In the absence of cortical hormones, the tubules are incapable of reabsorbing sufficient sodium and chloride from the glomerular filtrate to maintain normal electrolyte and water balance. The ability of the kidney to excrete potassium is decreased, and a rise in serum potassium follows.

All the biologically active corticosteroids increase the reabsorption of sodium and chloride by the renal tubules. There is a considerable difference in magnitude of effect. Hydrocorti-

sone has the least effect, while desoxycorticosterone and aldosterone have the greatest effect on sodium retention. The latter compound is at least 1,000 times more effective in this regard than is hydrocortisone. With the retention of sodium there is a reciprocal loss of potassium. Cortisone and hydrocortisone maintain cellular hydration at an optimum, while desoxycorticosterone leads to intracellular overhydration and water intoxication when used in excess. Aldosterone occupies an intermediate position.

Androgenic panel: This function is measured as 17-ketosteroids in the urine. The values vary with the method used. The excretion remains at a low level from birth to the age of 7 years (0.1-1.5 mg./24 hours). With the onset of puberty the values rise sharply until adult levels are reached (normal male average, 14 mg./24 hours; female average, 9 mg./24 hours). After the age of 50 years the excretion gradually decreases in both sexes.

In women the adrenal cortex is the only source of 17-ketosteroids from the testes and production of 17-ketosteroids from the testes and adrenal cortex is under the influence of the pituitary, disorders in anterior pituitary function affect the output. In primary hypothyroidism, liver damage, and malnutrition, the output of 17-ketosteroids is very low. Adrenal hyperfunction due to hypertrophy, adenoma, or carcinoma of the cortex results in high urinary values of 17-ketosteroids. The assay of the β -hydroxy fraction has been used as a means of differentiating between cortical hyperplasia and malignant tumors. This fraction is high when such tumors are present and is not raised when a benign tumor is present.

Diseases of the Adrenal Cortex

In this instance our concern is only with pathologic conditions of the cortex which result in hyperfunction. Hypofunctioning syndromes are not amenable to surgery.

Hyperfunction of the Adrenal Cortex. Hyperplasia, adenoma, or carcinoma of the cortex may be responsible for the clinical syndromes. Such diseases may be conveniently classified as follows:

1. Complete hyperfunction
- a. Cushing's syndrome

- b. Mixed syndrome
- c. Anterior pituitary basophilic adenoma
- 2 Partial hyperfunction
 - a. Adrenogenital syndrome
 - b. Pseudohermaphroditism
 - c. Feminization in the male
 - d. Adrenal hyperplasia associated with symptoms of Addison's disease

Cushing's Syndrome—This syndrome has been discussed under the pituitary gland (see page 385). Specific diagnostic aids with reference to adrenal pathology include the following.

1. Flat plate of the abdomen to note any abnormal shadows and position of the kidney.

Tomograms may be helpful; however, false positive interpretations may result as has been found for insufflation studies.

ACTH stimulation and cortisone suppression tests have been widely used to differentiate between adrenocortical hyperplasia and adenoma. Hyperplasia of the cortex will lead to a brisk response to ACTH stimulations (20 IU. q 6h for 48 hours), whereas administration of cortisone (25 mg. q 8h) or 9-alpha-fluorohydrocortisone (1 mg. b i d) will result in suppression of blood 17-hydroxycorticosterone and urinary corticoids. Adenoma or carcinoma of the cortex will show little change when such procedures are performed. Further work must

Fig. 210—Technique of presacral peritoneal insufflation of oxygen

The patient is placed in the knee-chest position, and the sacrococcygeal and surrounding area is cleaned and painted with Merthiolate solution. The patient is draped with sterile towels. The skin and subcutaneous tissue at the tip of the coccyx are infiltrated with 1% procaine. A No. 20 lumbar puncture needle is inserted just beneath the tip of the coccyx, then the direction altered so that the tip points dorsally into the hollow in front of the sacrum. When the end of the needle is felt to be in the sacral hollow, 1,500 ml. of oxygen are slowly injected. This diffuses upward and surrounds the kidneys and adrenals. The positioning of the patient controls the diffusion of gas.

2. Intravenous and retrograde pyelography which may demonstrate downward displacement of one kidney

3. Presacral peritoneal insufflation of oxygen. This procedure is sometimes helpful but in many instances results in either shadows being read as tumor when none was present or failing to demonstrate a tumor when such was present. The technique of this procedure is shown in Fig. 210.

be done before these tests can be interpreted with accuracy.

Mixed Tumors—This term is used to denote both androgenic and metabolic disturbances. In such instances the patient will usually present signs of virilization but of a milder degree than that seen in the adrenogenital syndrome (following), as well as some disturbance of carbohydrate metabolism, although less than is seen in Cushing's syndrome.

Fig 211 -Congenital bilateral adrenal hyperplasia The skin biopsy was examined by Dr Barr and the patient found to be a female She was 5 years of age

Fig 212 —A, Presacral air insufflation showing normal adrenals
B, Presacral air insufflation showing large, round shadow in region of left adrenal

The pathology present may be that of hyperplasia or adenoma. The hyperplasia may be unilateral. Rarely is it due to carcinoma.

The diagnostic procedures are similar to those which are necessary in the diagnosis of Cushing's syndrome.

Adrenogenital Syndrome.—Patients suffering from this condition are virilized. The term virilization refers to masculinization of the female with the result that there is loss of head hair, recession of temporal hair, acne, hirsutism, lowering of the voice, enlargement of the thyroid cartilage, amenorrhea, and enlargement of the clitoris. This syndrome must be differentiated from masculinization of the female caused by tumors of the ovary, such as arrhenoblastoma, luteomas, or hyperfunctioning Leydig cells in the hilus of the ovary. Pelvic examination, if necessary under anesthesia, will assist in excluding an ovarian tumor. The 17-ketosteroid excretion is not as high when an ovarian tumor is present as it is with an adrenal tumor.

Pseudohermaphroditism.—This condition is due to adrenal cortical hyperfunction in utero. It is said to be always due to hyperplasia. It must not be confused with true hermaphroditism which is a genetic abnormality.

When female pseudohermaphroditism is present the child is born with excess hair and undetermined sex. The clitoris is enlarged to penislike proportions. Sex may have to be determined by laparotomy, although the need for such has been greatly lessened by sex chromatin study (Barr and Marshall). This includes skin biopsy and blood or sputum studies. It appears that the combination of two X chromosomes (male) leaves a spot of sex chromatin below the nuclear membranes.

If the child is a female, a clitoroidectomy is then performed.

Due to the large amounts of androgenic substance secreted from the adrenal cortex, such children grow very rapidly, but unless treatment is instituted, there will be such rapid closure of the epiphyses that retarded growth will result.

Feminization in the Male.—Enlargement of the breasts and atrophy of the testicles are the outstanding features of this disease. In 11

recorded cases each had a malignant cortical carcinoma.

Treatment. When a definitive anatomic lesion is demonstrated by palpation or other means previously discussed, surgical removal is indicated. In many instances surgery is performed both as a diagnostic as well as a therapeutic measure.

Treatment of adrenal cortical hyperfunction by means other than surgery has not been successful except in the pseudohermaphrodite. In this disease 25-50 mg of cortisone administered orally each day will depress adrenal cortical androgenic function to normal.

X-ray therapy has been directed both at the adrenal and the pituitary. The administration of estrogens has likewise not proved successful.

Surgical removal of the adrenal gland may be done through (1) the usual lumbar incision as for exposure of the kidney, which gives relatively poor exposure; (2) thoracoabdominal approach by traversing the pleura and diaphragm, as described by Chute; or (3) a dorsal lumbar flap incision, in which the angles of the 11th and 12th ribs are removed, as described by Nagamatsu. This latter incision gives excellent exposure of the adrenal gland. It is felt that greater efficiency is attained if two teams of surgeons work simultaneously.

Preoperative and Postoperative Care.—If one adrenal is found to be normal, then the other adrenal must be explored. If an adenoma is found, extirpation is performed. If hyperplasia is present, then a bilateral adrenalectomy is the treatment of choice. It is well to assume that the patient will have no adrenal cortical function for at least 5-7 days postoperatively and therefore preoperative, operative, and postoperative treatment is necessary. Cortisone 25 mg is administered orally q 6h, beginning two days preoperatively. On the morning of operation 100 mg of cortisone is given intramuscularly. This is repeated in 8 hours' time. When the patient is able to swallow, cortisone may be given orally in 25 mg doses q 6h. for seven days postoperatively. If an adenoma has been removed, the cortisone is gradually reduced (12.5 mg. q d). If hyperplasia was found and bilateral adrenalectomy performed, the patient can be maintained on 25-50 mg of cortisone per day.

SURGERY OF THE ENDOCRINE GLANDS

If during the operative procedure the patient should collapse, 100 mg of compound F (hydrocortisone) may be given in the intravenous 5% glucose and saline

Fig 213 Gross specimen of adrenal cortical carcinoma and atrophied or congenital aplastic kidney

Blood Supply.—Branches from the inferior phrenic and renal arteries as well as the abdominal aorta maintain the blood supply. The veins empty into the inferior vena cava on the right and renal veins on the left.

Nerve Supply.—This is derived from the celiac and renal plexuses which in turn receive cholinergic fibers from T₅-L₁ via the splanchnic nerves. These fibers go through the cortex to the medulla. The secretion of epinephrine is greatly diminished when the splanchnic nerve is severed.

Physiology

Two hormones have been extracted from the adrenal medulla—Epinephrine and norepinephrine. A comparison of these two hormones is given in summarized form in Table 14.

Diseases of the Adrenal Medulla

Hypoadrenalism.—This is not an established clinical entity, although when there is cortical destruction, the medulla may also be destroyed.

Hyperadrenalism.—The only functioning tumor of the adrenal medulla is the pheochromocytoma. However, many other tumors occur, and these are discussed briefly. Considerable difficulty exists in understanding the nature of medullary tumors. This is due to the variety of different cell types which may be present in different parts of the same tumor or its metastasis. Cells may be found in all stages of development. The degree of malignancy depends upon the number of primitive cells present.

Adrenal Medullary Tumors.—See Tables 15 and 17.

Diagnostic Techniques.—These are essentially the same as those described for the adrenal cortex.

Treatment.—Surgical removal of the tumor is as described for the adrenal cortex. Preoperative and postoperative care of the patient in whom a pheochromocytoma is to be removed is important. Profound vascular alterations occur with surgical manipulation of the tumor. The patient may develop epinephrine

THE ADRENAL MEDULLA

Anatomy

At birth, the adrenal medulla is small and most of the chromaffin tissue exists as paraganglionic masses along the abdominal aorta. It is derived from ectoderm. The predominantly functional cell is the pheochromocyte. Sympathoblasts arise from sympathogonia which in turn arise from the neural crest. The subsequent development of the sympathogonia is as follows:

TABLE 14

	EPINEPHRINE	NOREPINEPHRINE

shock It is recommended that a continuous intravenous drip containing Regitine or Dibinamine be maintained in order to block the possible hypertensive episodes. Postoperative noradrenalin is helpful in overcoming the hypotensive phase which so often follows extirpation.

Metastatic Medullary Tumors—The "Pepper type" of metastases is considered to be due to a primary neuroblastoma of the right adrenal gland, with the bulk of the metastases occurring in the liver (This has been explained as being due to the fact that the right adrenal lies against the bare area of the liver and that the lymphatics of the right adrenal empty directly into the portal system.) The

"Hutchinson type" of metastases consists of a primary tumor of the left adrenal, with initial metastases to the skull and orbit. (This is explained on the basis that the lymphatics from the left adrenal gland ascend along the aorta to the thoracic duct and reach the skull sooner and more directly than when conveyed by the lymphatics of the right adrenal gland.)

Some authorities disagree with this concept, and statistics reported show that in 56 examples of the "Pepper type," the growth was found in the right adrenal in 27, in the left adrenal in 21, and was bilateral in 8. In 83 examples of the "Hutchinson type," the primary tumor was in the left adrenal in 38 cases, in the right adrenal in 35, and bilateral in 10.

ISLET CELL TUMORS OF THE PANCREAS AND HYPERINSULINISM

Islet cell adenomas were first described by Nicholls in 1902, but no mention of a functioning tumor was made until 1927, when Wilder et al. reported a case of islet cell carcinoma with liver metastases which produced hyperinsulinism and hypoglycemia. In 1929 Roscoe Graham successfully removed the first functioning benign islet cell tumor with a complete recovery of the patient.

Hyperinsulinism with its resulting hypoglycemia is caused by a hyperfunctioning tumor of the pancreas. It should not be confused with functional hypoglycemia which occurs as the result of a disturbance of the blood-sugar regulating mechanism. This latter syndrome usually occurs in patients with emotional instability and with an imbalance of the autonomic nervous system.

There are numerous causes of spontaneous hypoglycemia. The following classification developed by Conn gives a comprehensive outline of these causes:

- I Organic—recognizable anatomic lesion
 - A Hyperinsulinism
 - 1 Pancreatic islet cell adenoma
 - (a) Single
 - (b) Multiple
 - (c) Aberrant
 - 2 Pancreatic islet cell carcinoma
 - (a) Localized
 - (b) With metastases
 - 3 Generalized hypertrophy and hyperplasia of the islets of Langerhans
 - B Hepatic disease
 - 1 Ascending infectious cholangitis
 - 2 Toxic hepatitis
 - 3 Diffuse carcinomatosis
 - 4 Fatty degeneration or "fatty metamorphosis"
 - 5 Glycogenosis (von Gierke's disease)
 - C Pituitary hypofunction (anterior lobe)
 - 1 Destructive lesions (chromophobe tumors, cysts)
 - 2 Atrophy and degeneration (Simmonds disease)
 - 3 Thyroid hypofunction (? secondary to pituitary hypofunction)
 - Adrenal hypofunction (cortex)
 - 1 Idiopathic cortical atrophy
 - 2 Destructive infectious granulomas
 - 3 Destructive neoplasms
 - Central nervous system lesion (hypothalamus or brain stem, interference with nervous control of blood sugar)

- II Functional—no recognizable anatomic lesion but explicable on basis of unusual somatic function
 - A Hyperinsulinism (imbalance of the autonomic nervous system): hypoglycemic fatigue, nervous hypoglycemia; functional hypoglycemia; reactive hypoglycemia
 - Alimentary hyperinsulinism (rapid intestinal absorption)
 - 1 After gastroenterostomy
 - 2 After gastric resection (partial or total)
 - C Renal glycosuria (severe degrees of low renal threshold for dextrose)
 - D Lactation
 - E Severe continuous muscular work
- III Miscellaneous
 - A Factitious (surreptitious insulin administration)
 - B Postoperative hypoglycemia
 - C Severe inanition
 - D Unknown

Islet Cell Tumors

These tumors are uncommon, although nearly 300 cases have been reported since 1929.

Incidence.—They are found in one out of every 800-1,000 autopsies. They occur in all age groups and are equally divided between males and females.

Pathology.—Islet cell tumors may be benign or malignant or so-called borderline malignant in type and may be functional or nonfunctional. The following classification of islet cell tumors of Lopez-Kruger and Dockerty describes the various types which have been encountered:

1. Adenomas of islet cells with hyperinsulinism and hypoglycemia
2. Adenomas of islet cells without hyperinsulinism
3. Carcinoma of islet cells with hyperinsulinism
4. Carcinoma of islet cells without hyperinsulinism
5. Borderline malignant islet cell tumors with or without hyperinsulinism

The adenomas most commonly occur in the tail of the pancreas, which contains the greatest concentration of normal islet cell tissue. Tumors, however, also occur in the body, the head, and uncinate process, and even in aberrant rests of pancreatic tissue.

The benign adenoma is small in size and measures in diameter from 0.5-1.5 cm. It is dusky, reddish-gray in color, and at operation

shows up as a darker area in the surrounding normal pancreatic tissue. Microscopically, the tumor cells resemble normal islet cell tissue. These tumors may be multiple, and two or more adenomas have been discovered in 12% of cases. Malignant tumors are distinguished by an invasive pancreatic mass with regional and liver metastases. Occasionally, hyperinsulinism is caused by a diffuse hyperplasia of the islet cell tissue.

Clinical Features.—The symptoms are due to a low level of carbohydrate supply to the brain which results in decreased cerebral metabolism. The brain is unable to store glucose in any appreciable amount. As in anoxia, the higher brain centers show the most sensitivity to the hypoglycemia. Electroencephalographic studies will show typical tracings due to hypoglycemia which are almost identical to those of anoxemia. Pathologic changes in the brain, in the nature of a degeneration of nerve cells, have been found at autopsy.

The symptoms vary greatly from patient to patient and tend to progress in their severity. They occur after a period of fasting or after a period of exertion plus fasting, which tends to depress the blood-sugar level. In the early stages of the disease, the symptoms are subjective.

Moersch and Kernohan have divided the symptom complex into three stages. In the first stage, the patient is mentally and physically retarded with drowsiness and lassitude. There may be slight confusion, restlessness, and irritability. The second stage is one of excitement, as shown by a marked confusion, marked restlessness, agitation, pallor, and profuse sweating. The third stage is that of coma, with or without convulsions, which may be tonic or clonic, a positive Babinski may be present, and nystagmus and motor paralysis occasionally occur. The level of blood sugar that produces these symptoms varies from patient to patient. If the condition continues for a long time, permanent degenerative changes occur in the brain; the symptoms then become permanent and cannot be relieved by the administration of glucose. Many patients have been diagnosed as epileptics and have been treated as such for years. Hyperinsulinism may lead to obesity as the patient learns that

he can avoid or minimize an attack by frequent feedings of high carbohydrate foods.

Diagnosis.—Hyperinsulinism must be carefully distinguished from other causes of hypoglycemia, the chief of these being functional hypoglycemia. In hyperinsulinism the fasting blood sugar is low and to be diagnostic should be below 50 mg. per 100 ml. The symptoms occur after a period of starvation or exertion and increase in severity as time goes on. The 5-hour glucose tolerance curve is extremely variable and is of little value in the diagnosis of hyperinsulinism. This is possibly due to the fact that the hyperfunctioning islet cell tissue behaves in a similar fashion to a pheochromocytoma, having periods of marked activity with intervening periods of quiescence. Only after the liver store of glycogen is depleted does the typical hypoglycemic curve result.

In functional hypoglycemia, the patient is usually emotionally unstable. A long-standing anxiety tension state will very often produce a hypoglycemia of the functional type. In the majority of cases, the symptoms are subjective, but occasionally the objective signs of pallor, sweating, and agitation may occur. The attacks do not occur after fasting but usually occur 2-3 hours after a meal, particularly if it has been of a high carbohydrate content.

In contradistinction to the patient with hyperinsulinism, the patient with functional hypoglycemia has a normal fasting blood sugar. The 5-hour glucose tolerance curve shows a sharp rise in the first 2-3 hours which is followed by a drop to hypoglycemic levels. (Glycosuria may occur during the phase of the elevated blood sugar.) Before attempting a 5-hour glucose tolerance curve, it is essential that the patient be placed on a high carbohydrate intake for two days prior to the test. The symptoms of functional hypoglycemia tend to remain the same over a period of years. As in the case of hyperinsulinism, exercise will aggravate the symptoms. The patient with functional hypoglycemia often gives a history of poor dietary habits and frequently subsists on a small carbohydrate breakfast and lunch, leaving his major meal until evening. The symptoms can be prevented by an adequate balanced diet consisting of liberal amounts of protein.

The best means of differentiating the two conditions is a prolonged period of fasting which, at times, may need to be maintained for 48 or even 72 hours. If an organic hyperinsulinism is present the blood sugar will, in nearly every case, fall below 50 mg./100 ml.

Hypoglycemia due to hepatic disease can be distinguished by signs of severe liver disease and by liver function tests. The hypoglycemia of anterior pituitary or adrenal insufficiency can also be distinguished by a careful observation of the well-known stigmata of these diseases. Hypoglycemia is frequently observed after a subtotal gastrectomy and the 5-hour glucose tolerance curve shows hypoglycemic blood sugar levels, which may be accompanied by symptoms. This hypoglycemia is partly responsible for the late postprandial phase of postgastrectomy syndrome.

Treatment.—Once the diagnosis is certain, the tumor should be removed as soon as possible, principally because such a tumor may be malignant. Early operation is also important to prevent permanent brain damage and increasing obesity. Before abdominal exploration is attempted, the surgeon must be sure that the disease is of an organic nature and not a functional hypoglycemia.

The three points defined by Whipple should be observed before any operation is contemplated. (1) the attacks must come on after a period of fasting or after exertion, (2) the blood sugar level must fall below 50 mg./100 ml, (3) the symptoms must be relieved by glucose, given either orally or intravenously.

Preoperative Treatment.—The patient should receive a high caloric, high protein diet for several days prior to the operation. Intravenous glucose may be necessary the night prior to the operation and on the morning of the operation. Any electrolyte disturbances should be corrected by the appropriate measures.

Operation.—It is usually best to approach the pancreas through the gastrocolic omentum which is removed from the stomach, care being taken to conserve the gastropiploic vessels. However, in the case of a low-lying stomach, the approach may be more simply made through the gastrohepatic omentum. The anterior surface of the gland should be carefully visualized and palpated, starting with the tail and working toward the body and

head. If no tumor can be visualized or palpated, the body and tail of the pancreas should be mobilized to allow palpation of the gland between the thumb and fingers. Frequently, an invisible tumor may be discovered by this means. If nothing is found in the tail or body, the head of the pancreas must then be mobilized by reflecting the duodenum and pancreas toward the midline to allow bidigital palpation. A careful search for multiple tumors must always be made. It is important never to neglect an examination of the common sites of aberrant pancreatic tissue, for occasionally tumors can be discovered in such areas. This is particularly so if nothing is found in the pancreas itself.

Once located, the benign tumor usually can be easily enucleated. However, if it occurs in the tail of the pancreas, it is sometimes preferable to resect a portion of the pancreas with the tumor. If any suspicion of malignancy exists, a wide area of excision should be carried out. If metastatic carcinoma is present, a radical pancreatectomy together with resection of all metastatic tissue should be performed.

If no adenoma can be found either in the pancreas or in aberrant tissue, a resection of the tail and body of the pancreas should be performed in the hope of removing an occult tumor or a sufficient amount of hyperplastic islet cell tissue to effect a cure. If after such a procedure the symptoms still persist, a total pancreatectomy may be performed.

Supportive therapy during the operation should consist of whole blood and physiologic saline. Glucose-containing solutions should be carefully excluded until the postoperative hyperglycemic response is evaluated.

Postoperative Treatment.—Following the removal of a functioning tumor, a period of hyperglycemia develops which is usually transient in nature but, at times, is sufficiently prolonged and severe to require insulin control. Once the residual normal islet cell tissue, which may be atrophic because of its functional depression by the hyperfunctioning tumor, regains its insulin secretory power, the hyperglycemia disappears. Only rarely does a permanent diabetic state ensue.

Results of Treatment.—The results of removal of benign and borderline malignant

SURGERY OF THE ENDOCRINE GLANDS

adenomas are good if the operation is carried out before permanent brain damage has developed. However, resection of malignant tumors with metastatic spread gives little, if any, hope of a permanent cure.

Chapter 14

The Breast

Ray Lawson, MD.

Breasts are characteristic of the mammalian class of animals. Their function is to secrete milk for the nutrition of the young; but in addition, as a secondary female sexual development, they serve, in the human at least, as an attracting stimulus to the male. They are composed of epithelial elements, which are surrounded and supported by fibrous and fatty connective tissue—the stroma. In the active state the epithelial elements form compound tubulo-alveolar exocrine glands. In the resting phase no alveoli are present, they do not secrete, and thus they cannot be considered true glands. No true specific internal secretions have so far been identified.

EMBRYOLOGY

It is remarkable that while the breasts are the last glands to function in the adult, they are the first of the epidermal glands to appear in the fetus. The glandular part of the breast is derived from ectoderm, which grows inward in strandlike fashion. The supporting stroma is evolved from mesodermal subcutaneous tissue. As early as the sixth week, an ectodermal thickening or outgrowth is apparent on either side of the trunk. In the second stage this *milk line* atrophies except in the pectoral region. This subsequently grows inward, branching radially into 15-20 solid cords. These ectodermal cords eventually become the milk ducts and each represents one unit of breast tissue. They branch and subdivide and

at 7 months begin to canalize. At birth the depression from the epithelial ingrowth becomes a prominence forming the nipple.

ANATOMY

The size, shape, and structure of the breasts are extremely variable. The breast is situated, except for the prolongation of the tail, in the superficial fascia on the front of the thorax. From the sternum it extends to the midaxillary line and vertically from the 2nd to the 6th ribs. There is no capsule and the 15-20 radiating lobes are firmly imbedded in the superficial fascia by strands of fibrous tissue. These form the framework of the organ and are known as the ligaments of Cooper. They ramify throughout the breast substance and connect the skin to the deep fascia. These ligaments are very important from the standpoint of the diagnosis of malignant disease because when breast tissue becomes edematous as a result of lymphatic permeation and obstruction, these inelastic bands cause fixation and dimpling of the skin.

Each lobe of the breast is an independent gland composed of lobules. A lobule is made up of branching lobular ducts, the smallest of which are termed ductules. The ultimate terminations of the ductules during lactation are the secreting alveoli. The stroma immediately surrounding the smallest ducts and acini is termed the periductal or intralobular connective tissue and is a relatively cellular type.

of tissue subject to constant variations. The stroma associated with the nipple and lactiferous and larger ducts is much more dense since it is not subject to great change. This is termed the intralobar connective tissue. The fibrous connective tissue between the lobules is designated interlobular, while that separating the lobes is termed interlobar.

Relations.—The gland lies on the pectoral fascia. Posterior to the upper half is the pectoralis major muscle, while inferiorly are the serratus anterior, the external abdominal oblique, and upper part of the rectus sheath. The axillary tail (of Spence) is particularly variable in size and extent. It passes upward and laterally at the edge of the pectoralis major and on through the foramen of Langer of the deep fascia into the axilla.

Blood Supply.—The anterior perforating branches of the internal mammary artery, particularly the 2nd, 3rd, and 4th, supply the medial portion. The lateral aspect is supplied by the lateral thoracic from the second part of the axillary artery as well as by the lateral perforating branches of the corresponding intercostals. A point of surgical importance is the fact that the main arterial inflow is through the upper half of the breast. The venous drainage in general follows the course of the arteries. Enlarged bluish veins characteristic of pregnancy and lactation are often seen running independently in the subcutaneous tissues.

Lymphatics.—Detailed knowledge of lymphatic drainage of the breast is important, because the aim of cancer treatment is the removal not only of the breast itself but also of the associated lymphatic vessels and glands *en bloc*.

The lymphatic system of the breast originates in the interlobular spaces and on the walls of the lactiferous ducts and terminates in nodes in the axilla, thorax, and cervical region.

Superficial.—The plexus of small lymph vessels, which surround the acini, passes via the periductal lymphatics to the subareolar plexus. From here, efferent channels lead principally to anterior pectoral nodes along the lateral thoracic vein, at the edge of the pectoralis major muscle.

Deep.—Some vessels leaving the interlobular spaces and ducts pass posteriorly to the deep fascial plexus, in relation to the pectoral and serratus muscles. From the deep plexus, large lymphatic channels run to the regional lymph glands. The efferent vessels from fascial plexus can be traced in groups circumferentially like the spokes of a wheel.

1. Some vessels pass directly above, after perforating the pectoralis major muscle, and terminate in Rotter's and other interpectoral glands, which lie in relation to the pectoralis minor muscle. Efferents from here proceed to surgically inaccessible subclavian nodes.

2. From the medial aspect of the deep plexus, vessels pass inward, alongside the perforating arteries and enter the anterior mediastinal glands, particularly those along each side of the internal mammary arteries.

3. Some vessels from the deep plexus cross the midline and anastomose with the corresponding plexus of the other breast.

4. From the inferomedial part of the plexus vessels travel through the rectus fascia to the ligamentum teres and thence to the liver and abdominal lymph nodes.

5. On the lateral aspect, there are channels which pass inward with the intercostal blood vessels to terminate in a series of nodes which lie inside the lateral and posterior chest wall and also nodes in proximity to the aorta. This route may be responsible for some of the vertebral metastases so frequently seen in breast cancer.

6. The most important lymphatic drainage of the deep plexus is upward and laterally to the lateral pectoral nodes and thence to the axillary groups. Direct connections exist, however, from the breast to the axilla.

The lymph nodes of the axilla lie in relation to the axillary vein and its immediate branches, inside the deep fascia.

Both axillary and internal mammary nodes drain primarily into the base of the neck where the lymphatic vessels enter the confluence of the large veins. The internal mammary nodes can also drain by retrograde manner into the dome of the liver. It has been traditional to accept the premise that breast cancer is disseminated primarily by lymphatics and later by hematogenous routes after the

lymphatic vessels empty into the large veins. However, it is quite possible that a very large proportion of breast cancers spread primarily and directly by purely hematogenous routes, without lymph node invasion. Metastatic cells can easily pass through the lungs, so that all metastases can be explained by this route.

Nerve Supply.—The skin covering the breast is richly supplied with branches of the 4th, 5th, and 6th intercostal nerves. The glandular part receives autonomic fibers which run with the 2nd to 6th intercostal nerves. Smooth muscle fibers which erect the nipple are supplied by these autonomic nerves.

HISTOLOGY

The alveoli of the female breast are lined by cuboidal or columnar secreting epithelial cells which rest on the *membrana propria* in orderly fashion. During lactation, the mechanism of milk secretion involves constant exfoliation of these cells. Columnar epithelium lines the ducts as far as the lactiferous sinuses, and then it becomes squamous in character. In the ducts a reserve outer layer of low cuboidal cells supports the columnar epithelium. The stroma consists of fat and fibrous tissue and is contiguous with the surrounding subcutaneous structures, since the breast has no limiting capsule. Around the acini are so-called accommodative spaces consisting of loosely arranged connective tissue. Because the bulk of the breast is fat, the actual size bears no relation to the quantity of milk-producing structures. The normal male breast does not significantly alter throughout life but consists merely of a few small duct rudiments posterior to the vestigial nipple.

PHYSIOLOGY

Most breast derangements are in some way related to the varying cellular characteristics that result from constantly changing hormonal stimulations. A more detailed knowledge of breast physiology than space permits here should be acquired. With the onset of puberty, the female breast becomes subject to alternate hyperplasia and involution. The hyperplasia is characterized by a material increase in both the duct structures and stroma. In the cycles of

this process, which are coordinated with the menstrual periods, the phases of hyperplasia exceed the following involution phases until such time as the breast assumes adult size. When pregnancy occurs there is a tremendous wave of proliferative activity and many alveoli develop. In the later stages of lactation, regressive changes occur in which these racemose glands atrophy, and the acini disappear. Finally with the menopause, there is the onset of a gradual reduction in both parenchyma and stroma, until eventually nothing remains but a few dilated ducts and a small amount of fatty fibrous connective tissue.

EXAMINATION OF THE BREASTS

The student should adopt a routine method of examining all breasts, and the following outline is suggested.

The patient is undraped to the umbilicus and seated on the edge of the table or bed with the arms at the sides. The lighting must be adequate and free from distorting shadows. The breasts are first critically inspected and compared for size, contour, and symmetry. The arms are raised and the examination is repeated. Next, the nipples are examined for eczema and retraction. The examiner, standing behind the patient, palpates for supraclavicular glands, a sign of secondary spread.

Then with the pectoral muscles relaxed, by placing the patient's arm on one of his own, the axilla is gently palpated in all directions with the fingertips. Keeping the fingers here, the arm is swung back and relaxed as the axillary contents are palpated against the rib cage. The location, size, consistency, and fixity of any enlarged lymph nodes are noted. The fact that the result of a clinical search for involved nodes is unreliable is no excuse for neglecting this procedure, as positive findings are extremely significant.

Palpation of breasts should always be done gently and kept to a minimum for fear of spreading cancer cells. Only the flexor side of the extended fingertips should be used. The breasts are palpated with the patient sitting up and then again with the patient in a supine position with the side of the chest raised with a pillow. The whole of the breast structure

is investigated gently with the extended fingers. The most difficult area to palpate with accuracy is directly beneath the nipple.

The skin of the breasts is now examined for areas of retraction or fixation. Edema of the skin or "peau d'orange" from lymphatic blockage is a late sign and usually denotes an inoperable lesion. By gently pinching and lifting the skin, retraction or fixation of areas

iliac crest with the hand, or flexing the body on the hips with the neck extended.

Attention is again directed to the nipple, to test for the presence of discharge. This is done by stroking the breast with the index finger centrally over the skin, toward the nipple, in a circumferential manner. A milky discharge in a nonlactating woman usually does not have serious significance. About 5% of

Fig. 214—A, Preliminary inspection with adequate lighting. The breasts are critically inspected for contour, symmetry, and changes in skin.
B, Examination repeated with arms raised to accentuate latent deformities.
C, Careful palpation of the axilla, with relaxed pectoral muscles.
D, Gentle palpation of the substance of the breast with the finger tips. The thorax is elevated on a pillow.

is often elicited—a most important sign in cancer. Retraction is also elicited in other ways, such as raising the arms above the head, pushing the whole breast in each direction, compressing the breasts from both sides, contracting the pectoral muscle by pushing on the

of all breasts which have a bloody discharge will harbor carcinoma. But almost invariably in these cases a mass is palpable close to the areola, and the clinical diagnosis is evident. About 90% of nipples discharging blood will be associated with either papillomatosis or

ulcerating granulations, secondary to chronic duct dilatation or stasis.

Local x-ray examinations are of little practical help in examining the breasts. Rapid pathologic examination following punch or needle biopsy of lumps is being more frequently done as a routine preoperative measure in well-equipped clinics. This procedure is useful when applied to sites of secondary lymphatic spread, such as supraclavicular or cervical lymph nodes, to determine the state of operability when the diagnosis of breast cancer has been made. Papanicolaou smears of nipple discharge, properly interpreted, are helpful in detecting intraductal papillomatosis, but so far this method has been of no real assistance in the diagnosis of breast cancer. Aspiration of large cysts may relieve the discomfort from increased tension and effect complete disappearance of such lumps. When using this method, one must be aware of the danger of overlooking malignant disease and have the cells examined by a competent cytologist if the fluid is bloody or cloudy. The risk of disseminating cancer cells by needle biopsy is not a practical hazard, since follow-up surveys where needle biopsy has been done on cancer patients do not show an increased spread of disease.

Applications of various technologic measuring techniques in attempts to evaluate biologic changes of a dynamic nature rather than static anatomic differences are currently undergoing evaluation by several methods. Echographs made by measuring the reflection of sound waves are being explored but so far are of laboratory interest only. The study of altered heat patterns radiated by the skin in various wave lengths and detected by electronic cameras will likely contribute helpful diagnostic information.

In describing a lump in the breast, the following points should be noted: the size, shape, position, consistency, mobility, overlying skin dimpling, skin edema, nipple retraction, and nipple discharge. Most breast cancers are not clinically palpable until 1 cm in diameter. It is a sad fact that at this stage less than half the cases have strictly localized disease.

Every patient should receive a thorough radiologic examination of the chest, spine,

and pelvis before radical mastectomy is contemplated, so that distant skeletal metastases may, in some measure, be detected.

Enlarged lymph glands in the neck or supraclavicular region should be biopsied by needle technique if involvement is suspected.

CONGENITAL ANOMALIES

Amastia

Complete absence of a breast is rare and is usually found in males. It may be associated with the absence of the pectoral muscles or other congenital aberrations. An interesting hereditary pattern may sometimes be deciphered when this abnormality appears.

Athelia and Polythelia

Athelia is a rare condition denoting absence of the nipple, whereas polythelia, which is more common, refers to the presence of accessory nipples without breast tissue. Accessory breasts may be found anywhere along the mammalian *milk line* which extends from the axilla to the groin. Tumors can arise in these accumulations of breast tissue. Thus a primary carcinoma is occasionally seen in the axilla.

Gynecomastia

Gynecomastia is a true hypertrophy of mammary tissue in the male. The cause is often unknown, although trauma may be a factor, as well as hormonal disturbances. It may appear in men receiving estrogenic treatment for carcinoma of the prostate. It is also seen associated with hormone-producing tumors such as adrenocortical carcinoma, embryonal carcinoma, and especially chorionepithelioma. Testicular biopsies and blood estrogen determinations are occasionally of diagnostic significance in these cases. In the male, excision of such breast tissue may be warranted to correct discomfort or to alleviate embarrassment. Painful enlargements of the breasts are not infrequently seen in males at puberty. Such lesions should be treated conservatively, since they are due to a temporary hormone disturbance. The majority of patients with gynecomastia do not present any gross hormonal change. Impaired metabolism of estrogens by the liver and the vitamin B complex dietary

deficiency sometimes seen in liver disease can lead to gynecomastia. The important problem is to differentiate it from carcinoma, since about 15% of cancers occur in males. The effect of hormonal stimulation through the placenta is sometimes seen in the infant at birth. This is designated *mastitis neonatorum*. The discharge known as *witch's milk* has given rise in the past to superstitious phantasies, as the involved baby is usually the first-born and beyond term.

Virginal Hypertrophy (Macromastia)

This type of diffuse enlargement is usually unilateral. The cause is unknown. An abnormal breast of this nature seldom functions efficiently and is particularly prone to structural disease. Operative treatment may be indicated to alleviate embarrassment in extreme degrees of enlargement. This consists of intricate plastic procedures to reduce the size or simple mastectomy.

INFLAMMATORY LESIONS

Acute Infections

Acute breast infections may occur at any period of life but are generally associated with lactation. With modern methods of prevention and management, infections have relinquished the important and frequent place they formerly held in the realm of breast surgery.

The causative organisms should always be identified and tested for proper antibiotic therapy. Staphylococci are common offenders. The bacteria invade the breast through a crack in the nipple and pass inward by way of the ducts or the periductal lymphatics. A diffuse cellulitis is first established, but continuation of the infective process leads to localization and suppuration.

Three varieties of abscess formation are formally described, depending on location.

1. **Premammary abscess** may be subareolar or subcutaneous in position. Because of the location, there is no difficulty in the diagnosis. The classical signs of inflammation are present and the localized pus may be fluctuant. The pus should be aspirated and the cavity filled with the antibiotic of choice or simple surgical drainage performed. Premammary abscesses have a tendency to become chronic, but most

chronic recurring abscesses which point at the areolar margin are secondary to duct dilatation, stasis, and chemical mastitis. The irritating material filling the ducts ruptures through the ducts and causes an abscess which usually erodes through the areolar margin. Many of these are found in cases of congenital inverted nipples. In the chronic type, therapy consists of excision of the involved ducts and inflammatory mass, with plastic repair of the remaining areola.

2. **Intramammary abscess** is the usual type of acute breast infection and is located well within the substance of the breast tissue. It practically always results from lactational mastitis. The cavity is diffusely located and may involve one or more lobes. There is marked systemic reaction with fever and malaise. The localized inflammatory reaction is associated with induration of the breast. If the abscess is well developed, the treatment consists of operation under general anesthesia. A large radial incision into the abscess cavity is made and a finger is inserted to thoroughly break down the honeycomb type localizations to ensure complete drainage. The cavity is then packed with gauze, and the incision is left wide open. Dependent drainage with soft rubber tubes through a separate stab wound is often advisable.

3. **Retromammary abscess** is a localized infection in the areolar tissue between the chest wall and the breast. It is extremely rare and may be acute or chronic. The acute cases are typified by a much more intense systemic reaction with less apparent local signs. Such infections are usually secondary to subjacent lesions, such as empyema, tuberculous osteomyelitis of the ribs, or infected hematomas. The typical abscess eventually points inferolaterally, pushing the breast forward. Treatment consists of surgical drainage in addition to correction of the underlying lesion. A curved incision is made along the inferolateral aspect of the breast. The abscess is located with a pair of artery forceps and digitally explored. Gauze is then loosely packed into the cavity after the causative lesion has been suitably treated.

The most important aspect in the treatment of all puerperal breast infections is prophylaxis by careful hygiene. This includes careful

ness of the nipple, protection from trauma, and prevention of stasis by expression of the preliminary secretion. The use of antibiotics at the time of childbirth has been dramatically effective in reducing the incidence of these infections. If an acute infection occurs, the baby should be weaned, and the breast "dried up." The application of a firm protective breast binder and oral therapy with 5 mg of stilbestrol 3 times daily will adequately serve this purpose.

Chronic Infections

Tuberculosis, while rare, is responsible for the majority of chronic infections. It is usually secondary and occurs in women having open pulmonary lesions. The organism may gain entrance through a cracked nipple. A large tender mass of variable consistency is present, and it may be absolutely indistinguishable from carcinoma. Certainly in the early stages, the clinical diagnosis is impossible. The axillary glands are characteristically enlarged and, as the lesion advances, multiple draining sinuses appear. Treatment consists of wide *en bloc* excision of the area, including the overlying skin of the breast and the underlying costal cartilages, if involved. This can usually be done extrapleurally and without breaking into the abscess cavity. Closure is obtained by undermining the adjoining skin and subcutaneous fat and, if necessary, by rotating a skin flap to cover the defect. The general treatment of tuberculosis must be enforced, which includes rest, diet, dihydrostreptomycin, and PAS.

Syphilis of the breast is now a curiosity. As a primary lesion it appears as a chancre in the region of the nipple. It is single, unilateral, painless, and associated with rapid enlargement of the axillary lymph nodes. Diagnosis is made by the typical appearance and by dark-field examination of the exudate. In doubtful cases biopsy is necessary. The treatment is that of syphilis in general.

Actinomycosis is an extremely rare infection and is usually secondary to involvement of the lungs, with extension through the thoracic wall. It is characterized by chronically indurated areas and weeping granulation tissue which discharges sulfur granules through secondarily infected sinuses. Treatment is surgical

excision of the lesions, massive doses of iodides, penicillin, and other forms of chemotherapy as described in Chapter 3.

Eczema of the nipple usually clears up if mechanical irritation is avoided and the part kept scrupulously clean and dry. Cortisone preparations and tar ointments have been found useful. Should the eczema persist, Paget's disease should be suspected, and a wedge biopsy may be indicated to rule out this condition.

Other types of chronic inflammation such as sarcoïd, blastomycosis, filariasis, sporotrichosis, and leprosy have been reported.

CHRONIC MASTITIS (CYSTIC DISEASE)

The female breast is likely to be altered in structure in the first place, by fibrous involution with loss of parenchyma and, in the second place, by varying degrees of epithelial hyperplasia. These two types of changes often coexist in varying degrees and, so far as is known, are due to abnormal hormonal stimulations. When such structural changes are evident, we call the lesion *cystic disease*, or *fibroadenosis*, for lack of a better term. Despite the fact that the varied terminology so commonly encountered in reading descriptions of the different phases or degrees of these types of breast changes is extremely confusing, it is possible to orient and classify the progression of the abnormalities in structure in a more or less orderly fashion. Whether or not it is usual for cancer to evolve from the associated series of epithelial changes is a much debated point. Until this is settled the problem of properly treating the lesions called cystic disease remains difficult.

The fundamental changes consist of an increase in fibrous connective tissue with loss of parenchyma (epithelial elements). Obstruction of the lactiferous ducts by inspissated material, chemical irritation, or external pressure from fibrosis may result in the formation of cysts. Such cysts may reach considerable size and contain serous fluid under tension. According to a once popular pathologic classification, it was claimed that these cysts may be lined (in chronologic order) by compressed atrophic epithelium, a denuded fibrous mem-

brane, or by regenerated and hyperplastic epithelium. The lining epithelial cells when hyperplastic may form several layers inside the cysts or ducts, traverse the lumina, or fill them solidly. Further progression of epithelial changes has been described, in which the cells are considered malignant and the so-called *intraductal carcinoma* or *carcinoma-in-situ* is recognized. Since the diagnosis at this stage depends on cytologic changes alone, the borderline of malignancy cannot always be

tion of estrogenic substances. Warren's studies showed that women afflicted with cystic disease before the menopause were 11 2 times as likely to develop cancer as those in the general population. He found that after the menopause this danger was not appreciably increased. On the other hand, Bloodgood's school and other authorities, the weight of whose opinion cannot be overlooked, claim that the relationship between this condition and cancer is purely coincidental. Furthermore,

Fig. 215—Chronic cystic disease of the breast

sharply drawn. However, once these cells break the law, i.e., the growth extends beyond its normal boundaries into periductal tissue and lymphatics, the diagnosis of carcinoma is readily made on a topographic basis.

There is laboratory evidence to support the interrelation of the epithelial activity in cystic disease and the development of malignancy. Experimentally, in male mice, a similar series of epithelial changes, progressing to malignancy, has been reproduced by the administra-

our own and many other follow-up studies on women who have had breast biopsies which showed benign hyperplastic epithelial changes do not show any impressive increased incidence of malignancy.

Diagnosis.—This is a very common disease of apprehensive and tense personality types. More and more cases are being encountered because an increasing number of women with cancerphobia are seeking medical counsel. Cystic disease is characterized by nodular or

thickened areas in the breast which become increasingly painful before menstruation. The findings on examination are variable. There may be no cysts, or the cysts may be so small as to be imperceptible, or they may be as large as an egg and may be single or multiple. Large cysts often have a bluish translucency on surgical exposure and have been termed by Bloodgood, blue-domed cysts. Most areas of nodularity consist of fibrous involution and are found in the upper outer quadrant. The pull of gravity due to the upright position has been suggested as a cause for this. Benign epitheliosis *per se* is not a palpable lesion and can only be diagnosed microscopically. Unfortunately there is little clinical and pathologic correlation of hyperplastic epithelial states, and a part of the breast severely involved may feel more normal than an area only moderately affected. The actual incidence of this fluctuating disturbance in the adult female population is impossible to ascertain but appears to be extremely high.

Fig. 216—Common incisions used in breast surgery

Treatment.—Local excision of the diseased area is far from satisfactory. As the lesion is more diffuse than clinically apparent and medical treatment inadequate, the only cure is simple mastectomy. As a general measure this is obviously far too radical but may be warranted in cases presenting severe degrees of this disorder. The pain and tenderness may frequently be relieved by 50 mg progesterone vaginal suppositories inserted every second night for 5 doses. Many clinicians use methyltestosterone 10 mg daily by mouth, especially during the premenstrual phase, and one capsule of vitamin B complex 3 times daily. Additional therapy in the form of fluid and salt

restriction with the use of nonmercurial diuretics is sometimes helpful. Judicious use of ataractics may be beneficial. Hot compresses for severe pain, adequate support, and, above all, reassurance round out the treatment which, it must be admitted, is most unsatisfactory. While the somewhat increased incidence of cancer with cystic disease is generally recognized, clinical statistics do not support a radical approach just for the sake of the surgeon's and patient's "ease of mind." The patient's age, marital status, and familial history of cancer, as well as personal attitude, must be given individual consideration. Any "dominant" lumps or suspicious areas must *always* be excised and microscopically examined. It may be argued that biopsy may miss an important area. There is no answer to this argument. If the biopsy shows atypical, benign epithelial hyperplasia, some surgeons unhesitatingly perform prophylactic simple mastectomy. The clinical differentiation between benign and early-stage malignant lesions is frequently impossible, and experienced surgeons are constantly distressed by the number of patients with inoperable cancer who have been treated conservatively for cystic disease until the real diagnosis has become obvious. Every breast lump *must* be excised, but the real difficulty lies in the clinical distinction between a lump and an area of nodularity. It is impractical and impossible to biopsy all areas of thickening and nodularity in every breast, as the disease is so characterized by relapses and remissions that few breasts would escape the surgeon's knife at some time or other. Cystic disease has a remarkable tendency to resolve during the first three months of pregnancy. One should be extremely careful to search for a co-existing carcinoma if epithelial hyperplasia is detected in a biopsy specimen. A close, conscientious six-monthly follow-up of these patients must be undertaken in order not to miss more serious lesions.

BENIGN TUMORS OF THE BREAST

Nonindigenous benign tumors such as lipomas, chondromas, leiomyomas, granular cell myoblastomas, dermoids, and sebaceous cysts may occur.

Fibroadenomas make up about 15% of all breast tumors. This type is most often seen as a firm, round, mobile, encapsulated, painless mass, about 1/2-2 cm. in diameter, in women under the age of 25 who have not yet nursed. Such tumors may be single or multiple and are often associated with either localized or generalized cystic disease. They seem to arise from an overgrowth of the intralobular fibrous connective tissue. Treatment is local excision of the tumor, preferably under general anesthesia. The incision should be made radially from the nipple or along the inferior fold of the breast. In rare cases, cancer can be traced to proliferation of the involved epithelial cells and occasionally sarcomatous degeneration occurs in a fibroadenoma.

Duct papilloma generally grows slowly within a cystic dilation of one of the main ducts near the nipple and is characterized by a nipple discharge which is often bloody. They are usually nonpalpable, but the dilated duct containing them may occasionally be felt to be firm and round. If the tumor can be accurately delineated (by transillumination and digital pressure producing nipple discharge over a specific area), local excision is satisfactory as it is not prone to malignant change.

Duct papillomatosis is in essence an advanced type of cystic disease, with multicentric epithelial proliferations proceeding to the formation of papillomas. This lesion is characterized by nipple discharge which is often bloody. No tumor masses can be palpated. The treatment is simple mastectomy or preferably local excision of the main duct system through an 180 degree circumareolar approach.

FAT NECROSIS

Fat necrosis, although it is uncommon, should always be considered in the diagnosis of a breast lump. Clinically, the lump cannot be differentiated from carcinoma. Occasionally following a blow, the fat liberated from ruptured cells is saponified by circulating enzymes. The lipogranulomatous reaction associated with proliferation of fibrous tissue results in a firm, hard, generally painless lump of indefinite outline. Many cases appear to be unrelated to trauma. The condition is sometimes seen in

the dependent part of pendulous breasts and in some cases seems to be related to nonpurpurative panniculitis. The treatment is local excision of the mass for diagnostic purposes.

GALACTOCELE

This rare lesion forms a smooth, tense, rounded swelling in the breast during the second or third month of lactation. It is the result of blockage of a milk duct by scarring or local inflammation. Its recognition is important insofar as it may be confused with malignant disease. The treatment is repeated aspiration and support of the breast by a compression bandage. Occasionally it is advisable to arrest secretory activity of the gland by hormone therapy.

PLASMA CELL MASTITIS

Plasma cell mastitis is a rare lesion of the aging postlactational breast. It usually occurs in women 30-40 years of age. The exact etiology is unknown, but the condition is associated with advanced degrees of mammary duct ectasia. The inflammatory process probably represents a foreign body reaction to some chemical product of mammary secretion and is characterized by intense fibroplasia and the presence of large numbers of plasma cells. The onset is acute, with mild pain, tenderness, chills, and fever. A painless mass, 2-5 cm in diameter and resembling a malignant tumor, is usually palpable when the acute phase subsides. Biopsy is necessary to distinguish it from carcinoma. The condition may be a variant of chronic premammary abscess, as previously described.

MALIGNANT DISEASE

CARCINOMA

The understanding and control of cancer is the most urgent problem of medicine today. The collection of accurate data on such a complex disease is much more difficult than would at first seem apparent. Our information dates back to the Egyptian descriptions in 3000 B.C. Cancer was extensively discussed in the early literature of Persia and India. In 400 B.C. Hippocrates recognized abnormal growths which he called *Karkinoma*. Four hundred

FIBRO-ADENOMA

BENIGN
INTRACYSTIC
PAPILLOMA

stromal cells. Changes in cells of the pituitary glands have also been described as a common accompaniment to breast cancer. This further indicates the association of the disease with an abnormal hormonal background. Trauma, often related to the discovery of malignant disease, has not yet been incriminated as a definite etiologic factor. Lawsuits are sometimes dependent on this supposition.

Pathology.—The many diverse pathologic forms make precise classification difficult, but a relatively simple one is suggested. Often a combination of pathologic types is found in one section. It should be pointed out here that there is no definite histologic correlation between tumor type and long-term survival. Where the nuclear structure is characterized by anisonucleosis, with many nuclei being greatly enlarged, the chromatin coarse and clumped, the nucleoli prominent, and mitotic figures frequent, the prognosis is particularly poor. On the other hand, where there is much lymphocytic infiltration into the primary tumor and also increased reaction of the sinus histiocytes in the regional lymph nodes, survival time seems to be increased.

Scirrhous carcinoma is the most common type of breast cancer. It forms a stony hard tumor in which the dispersed epithelial cells grow in solid nests and columns. The malignant cells appear to be so compressed by the greatly increased fibrous tissue growth resulting from host reaction that there is no attempt at glandular formation.

Medullary carcinoma has a marked glandular proliferation with relatively little connective tissue. The lesion is soft and friable and microscopically consists of masses of large, round, epithelial cells. Medullary carcinoma has a relatively better prognosis. It seems to spread more slowly with larger involvement of solitary nodes. However, it has less local inflammatory tissue reaction.

Adenocarcinoma may be divided into the *mucoid type*, with its tendency to papilliferous change and the deposition of mucoid material, and the *ductal type*. The latter arises from the ducts of the breast parenchyma. Adenocarcinoma, while a relatively uncommon form of breast cancer, offers a somewhat better prognosis than does the scirrhous carcinoma.

In **intraductal carcinoma (comedo cancer)**, malignant cells at first remain confined to the ducts, and in this state the differential diagnosis between frank malignancy and carcinoma-in-situ may be exceedingly difficult. The differential diagnosis between carcinoma-in-situ and lesser degrees of epithelial hyperplasia may tax the resources of the most astute pathologist and cannot be accomplished in frozen sections. Pathologists naturally tend to protect themselves by labelling doubtful lesions malignant. Simple mastectomy is indicated for carcinoma-in-situ, as it is claimed that half of these lesions will become clinical cancer (intraductal) within five years.

Paget's Disease of the Nipple

Paget's disease of the nipple is a chronic intractable eczematoid change in the skin and occurs when a carcinoma close to the nipple has invaded and locally blocked the superficial lymphatic return. Cancer cells, which are here termed Paget's cells, invade the epidermis and become swollen and vacuolated. It is doubtful that the malignancy in these cases ever actually arises in the overlying squamous epithelium, but this point is occasionally subject to argument. The disease is from the outset a malignancy, and the treatment is mastectomy. Paget's disease metastasizes as infiltrating duct carcinoma. It has a better than average prognosis. The important point is that an area of eczema in the region of the nipple lasting 2-3 weeks should be biopsied. Similar lesions may occur elsewhere in the skin of the body. Ordinary benign eczema of the nipple usually responds promptly to local treatment such as wet dressings, antibiotics, or hydrocortisone ointment. On the other hand, Paget's disease is progressive.

Breast Cancer—Clinical Features

The problem of early diagnosis is in many respects insoluble. It depends on the connotation of the term. In the so-called early stages it is impossible to distinguish carcinoma from other breast swellings. Thus every lump in the breast of a woman must be considered as cancer until it has been removed and the proper

diagnosis has been made by histologic examination. Unsuspected breast cancers found accidentally have a remarkably good prognosis. Nodularity developing in one section of an otherwise normal breast may mask an early malignant change. A typical breast cancer is stony hard and is best felt by the flat of the hand compressing the organ against the chest wall. The edge of the tumor is vague and indefinite. With extension of the disease, there is ultimately skin involvement and local lymphatic occlusion with the development of peau d'orange. If the tumor is in the subareolar area, the nipple becomes retracted. Later the mass becomes fixed to the skin and to the pectoral fascia and muscles. If the tumor lies within, or has invaded one of the main ducts, there may be a nipple discharge, which is usually clear, but may be bloody. In the more diffusely growing forms, the tumor may involve the whole breast.

To assist in standardizing treatment and assessing results, four principal stages of breast cancer have been defined by Portmann. The limitations of any such gross artificial grouping should be at once apparent since the metastatic cellular nature of the disease does not allow accurate assessment.

Stage 1:

Tumor—localized in breast and mobile

Skin—not involved

Metastases—none

The treatment is radical mastectomy. After such treatment, 5-year survival may be expected in 70-80% of cases, and about 40% will survive 10 years. X-ray therapy should be unnecessary in this group.

Stage 2:

Tumor—localized in breast and movable

Skin—not involved

Metastases—a few axillary nodes, none elsewhere

With treatment as in Stage 1 with the addition of deep x-ray therapy, one may expect 25-30% 5-year survivals and about 12% 10-year survivals.

Stage 3:

Tumor—diffusely infiltrating breast, fixation to chest wall, edema of breast and/or secondary tumors

Skin—edematous, indurated, ulcerated and/or secondary nodules

Metastases—many axillary nodes involved or fixed but no clinical or x-ray evidence of remote metastases

While the outlook in this stage is hopeless, worthwhile palliation is sometimes achieved by mastectomy, but patients in this category are usually treated with x-ray and hormones.

Stage 4:

Tumor—as in any other stage

Skin—as in any other stage

Metastases—axillary and supraclavicular nodes extensively involved, clinical and x-ray evidence distant metastases

X-ray or hormone therapy may afford temporary palliation.

Survival statistics indicate that carcinoma occurring in the second breast should be dealt with as a primary lesion if evidence of other areas of involvement is absent.

In assessing end results and determining the value of treatment, it is necessary to compare the statistics with untreated cases. Medical literature contains observations on some 800 untreated patients, and it is doubtful if this group will ever be enlarged. The 5-year survival was 20% and the 10-year survival, 5%. Twenty per cent of the patients died during the first year. The average survival was 38.5 months after the lump was first noticed. Several cases are on record of persons living over 30 years with breast cancer. Good results are sometimes obtained by the treatment of late cases and poor results from the treatment of so-called early cases. The disease is extremely unpredictable, and late metastatic spread is seen more frequently in breast cancer than in any other type of malignancy.

One way of conveniently explaining the extremely diverse growth patterns of breast cancer as well as the unpredictability of therapeutic results is on the basis of *biologic predeterminism*. This thesis has been championed by Ian MacDonald of California. He contends that the clinical course in the individual case is determined before the symptomatic phase is reached and depends essentially on the inherent growth potential of the original tumor cell. While it is difficult to prove or disprove this contention, it might, in unthinking clinicians, promote an unjustifiably fatalistic attitude instead of stimulating therapeutic en-

thusiasm. An equally satisfactory and more constructive philosophy is the concept of *host resistance*. Unfortunately this is as yet a non-specific term, but it is likely that some of the many investigative projects now being pursued will illuminate and emphasize this avenue of thought.

Spread of Cancer

Cancer starts as a localized disease and with the passage of time spreads throughout the body. Some tumors behave almost like a syphilitic chancre, with widespread blood stream dissemination of cells almost before the primary growth is apparent as such. Other carcinomas seem content to remain localized indefinitely. The tumor spreads by direct extension when cell production is occurring at a faster rate than cell destruction, in other words when the growth is enlarging. The cells move along the lines of least resistance, like the crab they are named after; that is, along the tissue spaces. Surface tensions of the cell membranes are low, and they break away easily from the main tumor. They are capable of ameboid movements. Oxygen, glucose, and special nutritive materials probably attract these cells by chemotaxis toward the capillary loops, which are increased in number in the vicinity of the cancer. Although cells of breast cancer are about twice the size of red blood corpuscles, capillaries are quite distensible. Thus it is plausible that showers of cells are constantly being disseminated, not only by the lymphatics but also, directly, by the blood vessels. Tumor cells in peripheral blood have in fact been reported by some cytologists in a high proportion of breast cancer patients. Cancer growing in the medial half of the breast has a much higher rate of mediastinal gland involvement. The intrinsic lymphatic drainage in the breast is primarily to the subareolar area, so this area should always be widely excised in any operation for breast cancer, regardless of the location of the primary tumor. From the subareolar plexus, tumor cells pass deeply to the lymphatics lying on the pectoral fascia, and thence peripherally. The most obvious route is to the axillary glands and, secondarily, to the supraclavicular, infraclavicular, and cervical groups. Probably the lymphatics of the other breast form a primary target for

spread. It is impossible to tell pathologically whether a carcinoma in the other breast is primary or metastatic. Involvement of the other breast occurs in about 5% of operable cases. The other axilla is invaded early in a significant percentage. Lymphatic spread to the liver may take place via the lymphatics in the sixth interspace or by retrograde spread through the internal mammary chain which normally drains the dome of the liver. Clumps of tumor cells in either the pleural or peritoneal cavity frequently seem to break loose and grow at random on distal serosal surfaces. Lymphatic spread may cause a deposition of cancer cells in the skin, particularly in the area of the operation. Cells from intrathoracic involvement may pass to abdominal nodes by the lymphatics of the posterior part of the diaphragm. Breast cancer has an affinity for red bone marrow, and any bone in the body may be involved.

In patients dying from the disease, bone metastases are found in about 40%. The adrenals are invaded in half the cases and the other breast in at least 20%. In deaths from breast cancer, all patients have lymph node metastases, 65% have pleural invasion, and 60% liver metastases. Local skin occurrences are seen in about 40%. Brain metastases account for 12% of deaths. The actual dynamics of spread are not understood. A histologically normal endocrine system is rarely, if ever, seen in advanced breast carcinoma. It is likely that some chemical affinity for the cancer cells exists in specialized body tissues. For instance the pars nervosa of the pituitary gland commonly plays host to a metastasis, but this is not true of the pars anterior.

Although the majority of these tumor cells must be destroyed by unknown defense mechanisms or deteriorate after a sterile life, some must have the ability to lie dormant about the body for long periods of time ready to answer an appropriate summons for reactivation. Inanition, associated with disseminated pulmonary metastases, pleural effusion, anoxia, and pneumonia, seems to be the condition most directly related to death.

Treatment

The orthodox treatment of cancer has as its objective first the excision from the body of

cells that have taken on this new genetic behavior, and, if that is impossible, the use of any agent known or presumed to have a differentially destructive effect on the malignant cells. When this is impossible, there still remain medical and surgical measures for symptomatic relief which do much to make the final stages of this disease more tolerable.

Local disease is curable by adequate excision. In other words, if all the tumor cells lie within the tissue encompassed by surgical resection, cure is assured, and if not, failure is certain. The cornerstone of surgical treatment is a radical mastectomy as enunciated by Halsted in 1894. Although 5-year survival rates have shown improvement in some reports, it is a melancholy but undeniable fact that the average patient with breast cancer today does not seem to fare much better with respect to cure rate than did the patient of 60 years ago. This is due in some measure both to reluctance of the patient to seek early examination and to laxity on the part of the physician in insisting on thorough examination and early adequate treatment. No matter what personal philosophy we adopt about this disease, there is a substantially large group of cases that can be tremendously benefited by palliative surgery, even if cure cannot be obtained.

The clinical progression of disease in some patients is probably accelerated by growth of cells disseminated at the time of operative procedures, and some growths are so virulent that even the most careful surgery is not palliative but definitely harmful. Contraindications to radical surgery because of danger of spreading or causing acceleration of the disease and thus shortening survival time include acute (inflammatory) carcinoma, advanced disease with edema of the skin over the breast, and disease associated with satellite carcinomatous nodules in the skin. Where distant metastases exist, such as involvement of the supraclavicular glands, bones, lungs, and liver, operations to remove or prevent skin ulceration may occasionally be indicated, but x-ray and hormonal therapy are usually preferable. Inability to withstand surgery due to poor physical condition is an obvious contraindication to any operative attack on cancer.

Although a critical look at survival statistics indicates that about four out of five women with breast cancer will inevitably die from the disease, there are no grounds for adopting an attitude of therapeutic nihilism, since the palliative value of extirpative procedures has been clearly demonstrated to be very real. The term *operable* is often loosely used and means different things to different people. I should infer that the lesion may possibly be cured and at least the expected survival time of the patient materially prolonged, with relief of suffering and restoration of normal function.

X-ray Therapy

X-ray therapy is not curative, but tumor growth appears sometimes to be temporarily arrested and the life of the patient prolonged when it is properly administered. There is great variation in the radiosensitivity of breast tumors. The best response is from the more anaplastic types, despite the fact that they in general carry the worst prognosis. Exposure to radiation results in local arteritis, thrombosis, atrophy, and necrosis of tumor cells. Objections have been voiced from some quarters about the inadequacy of x-ray therapy alone and about the unpleasantness of radiation sickness and local skin reactions. However, its benefits should always be secured wherever possible in the treatment of all types of breast cancer.

X-ray therapy may be combined with surgery either before or after operation. Preoperative irradiation is administered with the intention of destroying malignant cells which may have spread from the primary tumor and of lessening the risk of spread at operation. In some advanced cases it makes surgical intervention feasible by reducing the growth of a relatively fixed lesion. The suggestion that valuable time may be lost and efficient wound healing jeopardized is probably overemphasized. In most centers, postoperative irradiation only is given in an attempt to destroy malignant cells which have been left in the operative field and those locally disseminated as a result of the operation. X-ray therapy is often effective in inhibiting the growth and pain of metastatic lesions. Pathologic fractures and osseous lesions occasionally recalcify following its judicious application.

Hormonal Therapy

From the vast amount of experimental work since World War II and the barrage of papers describing clinical observations, certain useful clinical data are coming into focus. We are becoming more aware of the greater importance of classifying tumors according to their biologic properties rather than on the basis of the unrelated histologic attributes. Thus has evolved the classification of estrogen and pituitary-dependent (or stimulated) tumors as opposed to hormone-independent tumors.

Estrogens.—

Deprivation.—About 40-50% of breast cancers in premenopausal women show a definite degree of estrogen dependency. In other words, these tumors will respond by increased growth to an increase in the level of circulating estrogens or with a temporary retardation or regression of the disease on removal of this growth stimulus. Unfortunately, methods of estrogen assay have not yet been developed to a satisfactory state for easy practical use. However, oophorectomy in premenopausal women is a useful adjunct to therapy. This may be done as a prophylactic measure at the time of the mastectomy, but most clinicians prefer to wait until the onset of metastatic disease, at which time it is termed a therapeutic castration. Although no difference in survival times can be proved, the reason for delaying is to better observe the effects of the procedure, since a patient who responds to therapeutic castration will likely respond subsequently to hypophysectomy. Irradiation of the ovaries is not nearly as satisfactory as surgical removal.

Administration.—Diethylstilbestrol 15 mg. is given daily until a total of 4 Gm. is taken. This treatment is reserved for patients 5 and preferably 10 years past the menopause. The tumor response improves with increasing age. Thirty per cent of patients show temporary regression of soft tissue lesions. Certain unpleasant side reactions can be expected. Temporary nausea and vomiting are encountered and are relieved by reducing the dose until tolerance is acquired. Uterine bleeding is the most troublesome phenomenon produced by estrogens. Outward signs such as pigmentation of the areola and axillary skin with breast en-

gorgement are often seen. While edema and hypercalcemia may develop in any patient with extensive bone metastases, these complications are sometimes precipitated by the administration of estrogen. They can be very serious and lead to anuria and death unless recognized and treated promptly. Patients placed on estrogen therapy should be conscientiously and closely watched for complications. The mode of action of estrogen is unknown, but the effects are considered to be mediated in some way by pituitary inhibition. Many authorities dogmatically state that estrogens should not be given for menopausal symptoms to women who have had breast cancer. The trained clinician uses the clinical response as the logical guide to hormone administration.

Androgens.—

Deprivation.—Following radical mastectomy for male mammary carcinoma, orchiectomy should be carried out. This is the situation in which hormone interference gives its best results in cancer therapy. Not only is the mechanism of action unknown, but no reasonable theories have yet been postulated to explain the effects.

Administration.—Androgens are given to the younger age groups of women in the form of testosterone propionate 150-300 mg./week, intramuscularly, for a period of 3 months. Although there are many unpleasant side reactions, over 50% of the patients are improved subjectively, with weight gain and relief of pain, and about 20% show recalcification of bone lesions. The chief unfavorable effects in order of frequency are hoarseness, hirsutism, increased libido, loss of scalp hair, acne, and the development of a ruddy complexion. The masculinization that androgens produce is so unpleasant that this hormone should not be given prophylactically. Androgens are more effective than estrogens in causing recalcification of bone lesions regardless of age, but there are cases where the growth rate of osseous metastases has been accelerated by androgens, with resulting hypercalcemia.

Adrenal Hormones.—

Deprivation.—Bilateral total adrenalectomy for advanced disseminated breast carcinoma has been studied and advocated by Huggins. It should be reserved for patients shown to have a proved hormone-dependent tumor. Sub-

jective response characterized by relief of pain and increased feeling of well-being has been obtained in 65% of patients and objective regression in 40%. The operative mortality is only 2.5%, but the patient must be maintained indefinitely on cortisone therapy in the range of 50 mg. daily. The good results from adrenalectomy are said to be due to more complete removal of estrogens from the body.

Administration.—Cortisone therapy causes some inhibition of both pituitary and adrenal secretions. This substance probably also acts peripherally by displacing estrogens at tumor target sites. Recommended dosage is 150 mg. orally per day for 3 days, then 50-100 mg. daily, depending on the degree of response. Hydrocortisone in four fifths the dosage is biologically equivalent. However, the delta steroids are preferable because of their freedom from salt-retention effects. Prednisolone 10 mg. is as effective as 50 mg. of cortisone and is slightly more active than prednisone. Worth-while remissions frequently occur even after the disease has become refractory to other forms of endocrine interference. Salt and water retention with pulmonary edema and cardiac failure, Cushing's syndrome, aggravation of diabetes, peptic ulceration, and osteoporosis, must be anticipated when using this therapy.

Hypophysectomy.—Removal of the pituitary gland for metastatic breast cancer was first performed in 1951. The rationale is that removal of the source of trophic hormones eliminates the release of steroid hormones from target organs. It is postulated also that a cancer-stimulating substance, possibly the somatotrophic hormone, would also be eliminated. However, the role of hypophysectomy in the treatment of advanced cancer of the breast is still in the process of being defined, and no satisfactory method of selection of cases is currently available. Premenopausal women responding to therapeutic castration and postmenopausal women demonstrating improvement from estrogen or androgen administration appear to respond favorably to hypophysectomy. It is not yet known whether this measure can produce an effect equal to the sum of oophorectomy and adrenalectomy. Although the evidence is not convincing, current trends favor hypophysectomy over adrenal-

ectomy. Practically all hypophysectomized patients show some degree of diabetes insipidus, and many require vasopressin. Nearly all require thyroid supplements. Temporary objective improvement is obtained in slightly more than 50%.

Hormonal therapy for breast cancer still remains a weak crutch on which to lean after surgery and irradiation are no longer of value. The dramatic effects sometimes encountered demonstrate the investigational value of these procedures and stimulate the search for new facts relevant to the nature of the disease.

Chemotherapy.—

Alkylating Drugs.—These are chemicals which are capable of the addition or substitution of an alkyl group in a compound. An alkyl group or radical is generally considered to be that unit which remains when one hydrogen atom is eliminated from a hydrocarbon, for example, methane (CH_4) \rightarrow methyl (CH_3) radical; ethane (C_2H_6) \rightarrow ethyl (C_2H_5) radical. It is alleged that some of these chemicals are particularly toxic to cancer cells during the phase of cell division, and certainly some show clearly demonstrable, though temporary, tumor-inhibiting effects in human beings.

Nitrogen Mustard, Sulfur Mustard, Triethylene Thiophosphoramide (Thio-TEPA), Tetramine, Triethylene Melamine (TEM), Busulfon.—This group of drugs, together with thousands of other cytotoxic chemical agents, is being studied, but all are of research interest only and should not be considered in routine therapy. Prophylactic chemotherapy at the time of cancer operations is currently under investigation. For instance, nitrogen mustard is being given by some groups intravenously with the idea of destroying dislodged cancer cells before they can take root.

Radioactive Phosphorus.—Radioactive phosphorus is given orally or intravenously to some advanced cases in the form of NaH_2PO_4 with the phosphorus made radioactive. Some bone lesions have an affinity for activated phosphorus which directly irradiates the tumor cells. Testosterone is used concurrently as a so-called matrix-fixing agent for the P^{32} .

Colloidal Gold.—Colloidal gold¹¹¹ is administered by direct injection for the local treat-

ment of pleural or peritoneal effusions where the tumor seedings are small and diffuse. The colloidal particles are small and effect local irradiation. If there are appreciable pulmonary components, this treatment must be supplemented by through-and-through external radiation therapy.

It is doubtful if any presently known compounds will have a permanent place in the chemotherapy of breast cancer

the diagnosis is confirmed, the instruments, drapes, and gloves are changed to lessen the danger of dissemination of tumor cells. A blood transfusion is started. The incision begins over the insertion of the pectoralis major muscle on the humerus, then proceeds inward and downward over the anterior chest wall on the lateral aspect of the breast, staying at least 2" from the edge of the tumor. Another skin incision passes medially to encircle

Fig. 218—Radical mastectomy

Radical Mastectomy

Radical mastectomy still remains the cornerstone of breast cancer treatment. The classical operation was first described by Halsted and is performed as follows. The patient is anesthetized, in a supine position, and draped with the appropriate arm abducted to 90 degrees. Unless previous needle biopsy has been done the mass is totally excised and examined microscopically to validate the diagnosis. If

the tumor. The skin flaps are developed with a sharp scalpel, keeping them as thin as is consistent with adequate circulation. This can be facilitated by lifting and stretching the skin edges with towel clamps.

The division of the clavicular and pectoral parts of the pectoralis major muscle is found and separated with the scalpel handle and followed down to the humerus. The head of the pectoral part is then detached at the hu-

meral insertion, and the muscle is reflected forward, exposing the pectoralis minor. The insertion of the latter is detached from the coracoid process and removed together with the surrounding clavipectoral fascia. The axilla is now accessible and its contents of lymphatic glands, fascia, and fat are carefully and thoroughly excised, working from the medial angle laterally. The axillary sheath must be opened as it contains many lymphatics. If possible, the long thoracic nerve to the serratus anterior and the nerve to the latissimus dorsi muscle are spared. Dissection is now carried down until both pectoral muscles are detached at their origins. The upper part of the fascia over the rectus abdominis is also removed. The mass of breast tissue and muscle is now discarded. A stab wound is made in the lateral skin flap for a long soft rubber drain. Difficulty may be encountered in skin closure because of the large amount of skin which must sometimes be removed. If closure is impossible without undue tension, a split skin graft should be taken from the thigh and sutured in place. A firm, well-padded dressing is now applied. The mortality resulting from this operation should not exceed 5%.

Arm movements are begun on the 5th or 6th day following inspection of the wound. On the 2nd or 3rd day, according to the amount of discharge, the drain should be removed, and by this time the patient is usually ambulatory. Sutures are removed from the 8th-12th day if the healing process has been normal.

A distressing complication of the operation of radical mastectomy is edema of the arm. This is caused by disruption of lymphatic pathways, low-grade infection, thrombosis of the axillary vein, or vascular fibrosis from x-ray therapy. It is treated by elevation, massage, or the use of an elastic arm bandage.

Simple Mastectomy

Since 1911, R. J. McWhirter, an Edinburgh radiotherapist, has been advocating simple mastectomy followed by x-ray therapy as a general treatment for breast cancer. His arguments have been based on two contentions. First, that while surgical intervention gives excellent results when the disease is confined to the breasts, the poor results from radical

mastectomy where the axillary nodes are involved may be due to surgical dissemination of cancer cells. Second, applying Dahl-Iversen's figures of metastatic spread, which showed 33% positive nodes in 48% when the axilla was involved, a remarkably small group was left which was potentially curable, having only axillary node involvement. However, his results in over 2,000 cases show a 42% 5-year survival which is not out of line with the results of the radical procedure. This approach has met with much opposition on the grounds that it ignores the established principles of cancer surgery and depends on a lymph node survey that included a high proportion of advanced cases. There is, however, universal agreement that this technique should be applied to poor-risk patients or those with borderline or inoperable lesions.

Superradical Mastectomy

Extension of the scope of the radical operation has received much extensive investigation, and ingenious methods have been designed to extirpate increased quantities of anatomic structures contiguous with the breast. Wangensteen's superradical mastectomy has been planned to attack the lymphatic nodes of the neck. His operative mortality and morbidity rates preclude the general adoption of this technique.

Jerome Urban of the Memorial Hospital for Cancer has applied a procedure permitted in his hands a safe *en bloc* resection of the chest wall including the internal mammary nodes. Although his series commenced in 1951, the rationale is soundly based and the results from the first 275 cases are promising but more time is necessary for its accurate appraisal. It is a logical type of extirpation when the primary growth is situated medially and the cases properly selected.

It is unlikely that any significant advance in the management of breast cancer will occur until such time as more fundamental information pertaining to the specific nature of the neoplasm is available. The student should be cautioned about the part played by external gymnastics and the careful selection of cases

where any optimism is shown in articles dealing with breast cancer, particularly in the competitive reporting of results. Constant suspicion leading to early diagnosis and the prompt institution of adequate surgery cannot be too strongly emphasized, for therein lies the only hope of cure.

SARCOMA

Sarcoma of the breast is uncommon and may assume a great variety of forms, varying in malignant propensities from relatively benign lesions to extremely malignant ones such as hemangioendotheliomas (angiosarcomas) for which all treatment even in the earliest stages is apparently hopeless. When cystosarcoma phylloides or giant fibroadenomas become malignant, 96% will become sarcomatous, while only 4% will show carcinomatous degeneration. Breast sarcomas occur mainly following malignant degeneration of benign

fibrous tumors. Treatment consists of simple or radical mastectomy. For lymphosarcoma, x-ray therapy is a valuable adjuvant.

Chapter 15

Thoracic Surgery

Stewart Baxter, M.D., and Darrell D. Munro, M.D.

INTRODUCTION

World War II and the years following have seen major developments in the field of thoracic surgery, the fundamental principles of which were established when diseases of the lung and pleura were first remedied by surgical means. Indeed, this specialty has matured and become parent to its offspring, the present-day cardiac surgery. Today every intrathoracic and chest wall structure is amenable to operative correction.

The modern concept of chest surgery includes the elimination or correction of the disease process, the preservation of maximum pulmonary function, and the eventual complete rehabilitation of the patient to an active and productive life. To accomplish this aim, the surgeon must completely understand the detailed anatomy of the pulmonary segment, which is the smallest functional and anatomic unit, and also the pulmonary and ventilatory function with the departures from normal caused by various disease processes.

ANATOMY

The lungs are subdivided into lobes, three in the right and two in the left, and each lobe is composed of primary units or segments. The key to understanding the segmental anatomy lies in the bronchial pattern of each lobe.

The air-conducting system, or bronchi, may be likened to a deciduous tree. Its leaves

are comparable to the clusters of alveolar sacs attached to the terminal twigs or branches of the bronchial system and oxygen is absorbed by these terminal structures. The complexity of this system is obvious, and variations from the normal occur. Nevertheless the pattern is remarkably constant when the intricacies of the branching systems of bronchi, arteries, and veins in the lung are considered.

Each bronchopulmonary segment possesses its own bronchial system, its own central pulmonary artery branch transporting unoxygenated blood to the segment, and its own peripheral vein draining oxygenated blood from the segment. Each segment is a separate functional and anatomic unit capable of performing independently and therefore amenable to surgical removal.

The most consistent anatomic structure in the lung is the bronchus with its branches; the most variable is the pulmonary venous system, while the arterial pattern is intermediate in this respect. The arteries are central in location and closely accompany the bronchi. The veins are peripheral, lying between and draining adjacent pulmonary segments, and are called intersegmental veins.

The standard nomenclature for denoting the branches of the bronchi is the *Jackson-Haber* classification. The trachea usually divides into a right and left mainstem bronchus at the level of the T4-T5 intervertebral disc. There are 10 segments in the right lung. Likewise there are, in effect, 10 segments in the left lung.

but on this side, two segments in each lobe originate from a single or common segmental bronchus, thus creating what is known as a compound segment. It follows then that on the left side, the number of primary segmental bronchi is reduced to eight. The next important point to realize is that the *lingula* of the left side corresponds to the middle lobe of the right side and constitutes the lower division of the left upper lobe.

The 10 segments in the right lung are distributed in the upper, middle, and lower lobes, respectively, according to the formula 3-2-5. These segments are named as one would expect, according to their anatomic location in the lobe with respect to the chest. Therefore, the three segments of the *upper lobe* are top, front, and back, or apical, anterior, and posterior. In the *middle lobe*, the segments lie side by side and therefore one is medial and one is lateral. In the *lower lobe*, the group of basal segments, four in number, is crowned by a single segment which is perched on top of these like a cone. This segment is uppermost in the lower lobe and is known as the superior segment, which must not be confused with the apical segment of the upper lobe. Below this, the basal segments are in anterior, posterior, medial and lateral positions, hence are so named. Thus, by consulting Fig. 219, the student can readily fix in his mind the segmental anatomy of the right lung, which is the key to the left.

The segmental anatomy of the left lung is now readily understood. You will recall there is a compound segment in the upper lobe and one in the lower lobe. In the *upper lobe* the apical and posterior segments arise from a common stem bronchus before its division, and therefore this compound segment is designated apical-posterior. In the lower lobe it is the anteromedial segment that is compounded. The one remaining difference is that in the *lingula* of the left upper lobe, which corresponds to the middle lobe of the right side, the segments are placed one on top of the other instead of lying side by side and are therefore called the superior and inferior segments. Nomenclature of the left side is as follows: the *left upper lobe* is divided into two main divisions, the upper division and the lower division. The upper

division, corresponding to the right upper lobe, is subdivided into the apical-posterior segment and the anterior segment. The lower division, which is the *lingula*, has two segmental divisions, superior and inferior segments. The *lower lobe* is quite similar to that on the right side. The superior segment of the lower lobe again sits on the basal segments which consist of the compound anteromedial and the posterior and lateral basal segments.

One should visualize rather than memorize this segmental anatomy, which will facilitate the segmental localization of disease seen on x-ray. The internal topography of the openings of the segmental bronchi is an important study which must be mastered before diagnostic bronchoscopy is attempted. This will be described in detail in the section on bronchoscopy.

The branches of the pulmonary arteries are named in exactly the same manner, for they accompany the segmental branches of the bronchi. Thus on the right side there are 10 main subdivisions of the pulmonary artery, each accompanying the bronchus. The pulmonary artery and its branches are mainly a transporting system and serve to carry unoxygenated blood from the right ventricle to be distributed to the dense capillary network in the alveolar walls. The pulmonary arteries are nutrient for only a minor fraction of the pulmonary parenchyma, and therefore one may ligate and sever the main pulmonary artery without subsequent necrosis of the lung. The pulmonary veins begin in the distal branches of the pulmonary capillaries and coalesce with larger branches, eventually reaching the hilum. They carry oxygenated blood to the left side of the heart for distribution to the remainder of the body.

The bronchial arteries are nutrient to the bronchi and a major portion of the lung parenchyma, and generally one is on the right and two are on the left side. They originate directly from the thoracic aorta on the left and usually from the first intercostal artery on the right, supplying oxygenated blood and nutrition to the bronchial system as far as the peripheral respiratory bronchiole and alveolar ducts. They also nourish the bronchial glands, visceral pleura, pericardium, nerve

plexuses, esophagus, and the coats of the pulmonary vessels. Most of the blood brought to the lungs by the bronchial arteries returns by way of the pulmonary veins; the rest returns by way of the bronchial veins which, in general, correspond to the bronchial arteries

there is a free peripheral anastomosis between the bronchial arterial capillaries and the pulmonary venous capillary bed.

The lymphatic drainage of the lung provides an interesting anatomic study, particularly with respect to primary neoplastic disease. The

Fig. 219—Lobes and bronchi of right lung according to the Jackson-Huber terminology

but are not well-defined anatomic structures. On the right side they empty into the azygos vein and on the left side either into the superior intercostal or the accessory hemiazygos vein. There are no anastomoses between the bronchial and pulmonary arteries. However,

vessels originate in two plexuses, the superficial and the deep. The *superficial plexus* lies on and beneath the visceral pleura and fans out beneath this membrane, draining toward the hilum to empty into the hilar glands. The *deep plexus*, consisting of a bronchial and a

vascular group, is responsible for draining most of the lung parenchyma. They follow the terminal twigs and branches of the bronchi and vessels along their segmental divisions to the larger nodes at the root of each lung. For practical purposes, no anastomosis occurs

that are distributed along and adjacent to the branching bronchi. Characteristically, these small peripheral nodes are located in the angles at the points of bronchial division. As the efferent lymphatic channels pass toward the hilum, the nodes are progressively larger.

Fig. 220—Lobes and bronchi of left lung according to the Jackson-Huber terminology

between these two systems. They both drain centrally, the superficial around the rim of the wheel and the deep along the spokes to the central hub or root, where anastomoses may occur. From the lung parenchyma the deep channels drain successively into lymph nodes

At the main lobar bronchi, the nodes are grouped as a ring around the bronchus. The lymph nodes along the roots of the smaller bronchi are known as the *pulmonary nodes* and those around the main lobar bronchi as *bronchopulmonary nodes*. From the broncho-

pulmonary nodes, efferents pass to nodes at the main bifurcation, the *interbronchial nodes*, and also to nodes around the roots of the great vessels. From here they drain centrally to the *tracheobronchial nodes* situated in the angle between each mainstem bronchus and the trachea. Thence, efferents pass upward

fact has been established. A cross-drainage exists from the left lower lobe by which the lymphatic channels drain directly upward in lymphatic channels in the deep left cervical chain or can cross over via the subcarinal channels and drain into the right cervical chain. This, of course, has a direct influence

Fig. 221 —The lymphatic drainage of the lungs, pleural spaces, and pleurae
A, Centripetal lymph flow to hilum and deep cervical nodes
B, Diagrammatic cross-section showing details of lymph plexus drainage

along the trachea, where they are known as the *paratracheal nodes*. The lymphatic drainage from the lungs eventually empties into the deep cervical group (*supraclavicular nodes*) at the root of the neck and from here into the venous system. One important anatomic

on the route of lymphatic spread in cancer of the left lower lobe. Therefore it must be remembered that all the lymphatic drainage of the right lung drains into the right deep cervical nodes; the lymphatic drainage of the left upper lobe drains into the left deep cer

vical nodes; but lymphatic channels from the left lower lobe may drain into either side. A better understanding can be obtained by a study of Fig. 221.

It is appreciated that there is an unusual anatomic situation in the lung whereby all the lymphatic drainage must necessarily pass through a very small neck on its route centrally and upward to the mediastinum and base of the neck. This anatomic site exists at the primary hilum, in the area immediately surrounding each mainstem bronchus. Therefore, despite the widespread prevalence of pessimism surrounding cancer of the lung, there is an unusual anatomic advantage in the surgical excision of a primary tumor and the ablation of its lymphatic drainage at its site of exit from the lung involved. It must also be mentioned that while the lymphatic drainage of the lung itself is always upward, that of the pleural space and parietal pleura is along the intercostal channels, posteriorly to nodes in the posterior intercostal spaces, anteriorly to nodes in the parasternal area along the internal mammary chain, and downward to nodes in the paravertebral areas and beneath the crura of the diaphragm.

The innervation of the lung is still far from understood and contains many mysteries. However, the nerves are derived from the autonomic nervous system, from both the parasympathetic (vagus) and the sympathetic divisions. These systems supply anterior and posterior pulmonary nerve plexuses which send fibers outward along the root of the lung to the bronchial walls, to the alveolar sacs, and to the pulmonary vessels. The nervous control of the pulmonary capillary bed has not been elucidated and is one which may ultimately prove to be of extreme importance. It is here that a buffer of the pressures between the pulmonary and systemic circulatory systems exists.

PHYSIOLOGY OF THE THORAX

The outstanding feature which distinguishes the pleural space from all other body cavities is the negative subatmospheric pressure which is normally present. This is produced by (1) the changes in the intrathoracic volume brought

about by the excursion of the chest wall during inspiration and expiration, and (2) the inherent elastic recoil of the lung. This negative pressure averages minus 6-9 mm of mercury at the end of inspiration and minus 4-6 mm at the end of expiration.

Pulmonary ventilation, on which life depends, cannot occur unless expansion of the thoracic cage is followed by inflation of the lung. If the pleural space is open to the atmosphere, an inspiratory effort will cause the suction of air into the pleural space with resultant lung collapse, adequate ventilation then becomes impossible.

It is important to emphasize that a unilateral pneumothorax will result in a reduction of the negative pressure in the opposite pleural space. This is caused by movement of the normally mobile mediastinum toward the intact side, the resultant reduced pulmonary volume of which decreases the vital capacity and tidal volume.

During inspiration the thorax is enlarged by the upward and outward expansile movement of the ribs and by the descent of the diaphragm which create a lower pressure in the alveoli, and air flows from the atmosphere through the tracheobronchial airway into the alveoli.

Since the lungs are normally elastic, the work of inspiration is mainly expended in overcoming the resistance of the lungs to expansion. At the end of inspiration the chest wall relaxes, and expiration occurs as a passive phenomenon. During any respiratory cycle the work involved to cause lung ventilation may be divided into (1) the work used to expand the lung against its elastic recoil (compliance), (2) the work necessary to overcome functional losses within the system (a very small component), and (3) the work necessary to overcome resistance to air flow throughout the tracheobronchial tree.

Open pneumothorax implies the presence of free air in the pleural space, with entry and exit through a chest wall defect with each phase of respiration. If the defect equals or exceeds the tracheal airway in size, more air will enter the pleural space than the lung

Closed pneumothorax implies the presence of free air in the pleural space, the amount of air remaining constant. Such a condition is usually well tolerated, since the movements of the chest wall still produce a swing in intrapleural pressure. The ventilation which is possible depends on the degree of pneumothorax present.

In *tension pneumothorax* a valve action exists whereby air enters the pleural space on inspiration and cannot be expelled during expiration. This situation is the result of a flap valve wound. Air continues to be sucked into the chest with each inspiratory effort, the negative pressure becomes completely abolished, and in a short time a high positive pressure develops. Complete collapse of the lung results with marked mediastinal shift and consequent compression of the opposite lung. Serious dyspnea ensues, and as respiratory effort increases, more air enters the space and a vicious cycle is established. This is an emergency requiring immediate decompression by needle aspiration or catheter drainage and the prevention of further air entry through the defect by surgical closure or suitable dressing.

PULMONARY FUNCTION TESTS

A number of physiologic tests have been developed for the qualitative and quantitative assessment of pulmonary function which have proved to be of great value in diagnosis, assessment, and treatment of surgical patients with cardiopulmonary disorders.

A specific enquiry with regard to *dyspnea* is of fundamental importance, and this provides good evidence of the patient's cardio-respiratory powers. The ability to climb stairs and the mobility of the thoracic cage on deep breathing should be studied.

Radiologic evidence of parenchymal disease, pleural thickening, and spinal and chest wall deformities generally signifies some limitation of function. The diaphragmatic and chest wall mobility should be noted on fluoroscopy.

The *maximum breathing capacity* (MBC) is the simplest and most universally applicable and provides a measure of the ability of the patient to move air in and out of the lungs with maximal respiratory effort. It is expressed as the number of liters of air per minute.

Comparisons are made of the result obtained with average normal values for persons of similar age and stature. The accuracy of this test depends largely on the patient's cooperation, the skill of the technician, and the type of apparatus.

The *vital capacity* is much less useful as a test of pulmonary function and is a measure of the greatest amount of air that can be exhaled after the deepest possible inspiration. It may be a misleading indicator of pulmonary function; e.g., in *emphysema* a relatively normal vital capacity may be present with a low maximal breathing capacity.

The *time vital capacity* is a measure of the maximal amount of air that can be exhaled in relation to time. Normally 95% is expelled in the first 3 seconds; lower values indicate an obstructive element in the expiratory phase e.g., in bronchospasm as occurs in asthma and chronic emphysema.

Bronchspirometry enables the respiratory function of each lung to be measured separately. Using this method the oxygen uptake, carbon-dioxide elimination, vital capacity, and ventilation can be determined. Of these factors, the oxygen uptake is the most useful indicator of the contribution each lung is making to the over-all pulmonary function.

Further information of value may be obtained by calculating the *ventilation equivalent*, i.e., the number of liters of air breathed per 100 ml of oxygen consumed.

In complicated problems more complex measurements of pulmonary function may be required. These include the measurement of the *pulmonary diffusing capacity* and analysis of the *blood gas content* of an arterial blood sample. The first of these measurements will reveal whether there is any barrier to the passage of oxygen from the alveoli into the blood and whether the surface area for oxygen exchange within the lung is adequate. This measurement is important in problems of pulmonary fibrosis and in chronic emphysema. The *oxygen saturation of arterial blood* will help to reveal the presence of any considerable shunt of blood within the lung or whether there is inadequate oxygenation of blood passing through lung alveoli. It is important to

realize that there may be considerable impairment of pulmonary function and disabling dyspnea without any gross change in arterial saturation

It has become increasingly apparent that the determination of *carbon-dioxide tension of the arterial blood* is vitally important. This is particularly true in the immediate postoperative period, when the patient may fail to ventilate the lungs adequately. This hypoventilation will very rapidly bring about carbon-dioxide retention. It must be emphasized that this potentially dangerous condition may be present although the patient's color when breathing oxygen is satisfactory. An elevated arterial carbon dioxide, if progressive, will result in stupor, progressing to deep coma and ultimate death. It is likely that many postoperative deaths, particularly in the older age groups, terminating in coma, are due to this sequence of events. To reverse the carbon-dioxide retention, one must provide adequate and efficient ventilation by cleaning the bronchi and improving all mechanical factors to assist air exchange. It may be necessary to use a mechanical respirator for this purpose, and a tracheostomy may be indicated. This diminishes the dead respiratory space, improving alveolar ventilation and, in addition, facilitates bronchial aspiration.

INVESTIGATION AND DIAGNOSIS OF A CHEST CASE

History and Physical Examination

A few leading questions may indicate the nature of the underlying disease. *Cough* is one of the commonest symptoms. Normally, this is a reflex mechanism for the expulsion of secretions and foreign material irritating the bronchial mucosa. It may be a dry, nonproductive cough which is produced by an intrinsic tumor in the lumen of the bronchus, or by extrinsic pressure as a result of enlarged mediastinal and peribronchial lymph nodes such as occurs in Hodgkin's disease.

A cough which is productive is most important, and the character of the *sputum* must be carefully noted. Sputum may be measured by collecting it in a single container to estimate the daily volume. In severe bronchiectasis

there is copious mucopurulent secretion. Blood expectorated in the sputum is as serious a sign as hemorrhage from any other mucosa-lined tract of the body. The production of bloody sputum or hemoptysis indicates a break in the integrity of the mucous membrane of the respiratory tract and may result from severe infection such as occurs in bronchiectasis, foreign body erosion, ulceration in endobronchial tuberculosis, rupture or erosion of a large blood vessel in a tuberculous cavity, or, finally, from the friable vascular surface of an ulcerating neoplasm. One must not accept the patient's statement that he has not expectorated blood, for often his observations are not reliable since, to him, blood in the sputum usually means a gross amount thereof. The patient should be specifically asked: "Have you ever noticed any streaks or specks of blood in your sputum? Have you paid particular attention to this detail?" If not, he is instructed to do so.

Chest pain may be of the typical pleuritic type which is aggravated by deep breathing or coughing. Another type is a constant, boring, severe pain due to malignant invasion of the chest wall itself. Referred pain around the chest wall from nerve root pressure and other extraneous sources must be elucidated.

The presence or absence of varying degrees of *shortness of breath* must be ascertained and carefully assessed as to the extent of disability it produces. Another significant sign, and one which is often neglected, is the presence of a *persistent unilateral wheeze*. To elicit this sign, one must ask the patient to forcibly expire the maximum amount of air, because frequently this sign is present only at the end of forced expiration. Sometimes there is a history of a persistent unilateral wheeze which had been present for a number of weeks and then completely disappeared. In such a case there has been a narrowing of the bronchial lumen to the critical point where air passing through the narrowed orifice is set in vibration, producing the wheeze which will disappear when the occlusion becomes complete. A persistent unilateral wheeze, or one which has been transient and disappeared, is generally due to an organic obstruction in the bronchus.

As in any examination, the *patient's color* is of importance. *Hoarseness* is another significant sign. It denotes invasion or compression of the recurrent laryngeal nerve by tumor. The presence of *fever* indicates an infection. *Weight loss* has been a time-honored symptom indicative of lung cancer, and if such has occurred, it usually is a late sign of widespread metastases. Apart from the purely metabolic effect of the carcinoma, there is no particular reason why a patient should lose weight unless such a cancer is producing obstruction with pneumonitis and chronic suppuration or widespread metastases. *Acute swelling and pain in the joints* are of special significance. Diseases of the chest are prone to be accompanied by a form of rheumatism known as *pulmonary osteoarthropathy*. It occurs occasionally in carcinoma of the lung. Recently, it has been recognized that the nervous system may be affected in cases of pulmonary carcinoma; a neuropathy with muscle weakness and sometimes frank paralysis occurs. In such cases no organic lesion can be demonstrated in the central nervous system. The mechanisms for neuropathy and osteoarthropathy are unknown.

In the physical examination, besides the findings by percussion and auscultation, a few points are of extreme importance. Particular attention should be paid to the lymphatic *drainage stations of the lung*. The accessible and palpable areas are the supraclavicular fossae. To be properly examined, the patient must be seated, with the examiner standing behind with one hand on the patient's head and the other palpating the supraclavicular and deep cervical chain. With the head turned toward the side being examined, the strap muscles can be relaxed, and deep palpation in the fossa may reveal the presence of hard nodes. If such is the case, a biopsy with microscopic examination may reveal the nature of the disease process. This is particularly true for cases of Boeck's sarcoidosis, Hodgkin's disease of the mediastinum, and cancer of the lung. The presence of digital clubbing, cyanosis, and swelling of the joints should be noted. The general examination should exclude the presence of enlargement of the liver and any other palpable masses.

Radiologic Examination

A good radiologic examination, with films of high quality, and a radiologist familiar with the detailed appearances of chest x-rays are absolute prerequisites to diagnostic work of high quality. *Routine plain x-rays* of the chest often indicate a diseased state. *Fluoroscopy* is used to determine the movements of the diaphragm and chest wall, the air entry and exit, the movements of the heart and of its chambers, as well as the configuration of the barium-filled esophagus. The presence of a paralyzed diaphragm can be verified by this method. The *tomogram (planigram)* is a method of examination whereby for predetermined planes, at depths usually 1 cm apart, films in sharp focus for the set level are obtained, the remainder being blurred. This is achieved by a specialized technique whereby the rays cross one another at a critical focal point, which can be adjusted at varying depths throughout the chest. With such a series of films it is possible to show in detail the structures at each particular level, the exact anatomic site of disease, and also the degree of lymph node involvement.

The *bronchogram* is valuable in outlining the bronchial system. A radiopaque substance is instilled into the bronchial tree and flows with inspiratory movements and by gravity along the mucosal lining into the peripheral branches. Abnormalities such as dilatation, bronchiectasis, obstruction, the presence of anomalies, and enlarged lymph nodes can thus be accurately identified. The newer water-soluble dyes are preferable because they are completely absorbed and do not leave residual opacities that obscure later x-ray studies.

Barium swallow may be indicated in any disease of the mediastinum to outline the position of the esophagus and its relation to the disease process, in addition to any intrinsic esophageal disease. It is also used to outline the posterior border of the heart to demonstrate chamber enlargement. In many cases of bronchogenic carcinoma it is employed to exclude involvement of the esophageal wall by direct invasion and to demonstrate the presence of enlarged lymph nodes producing compression defects.

Pulmonary angiography may be employed to diagnose and assess such conditions as arteriovenous aneurysm, abnormalities of the pulmonary vascular bed, the extent of the spread of bronchogenic carcinoma, displacement caused by mediastinal tumors, and secondary node invasion of the heart and major vascular structures

Endoscopy

In some cases, although the chest x-ray is reported normal, bronchoscopic examination will reveal the presence of serious disease. The direct observation of the air passages and their ramifications presents a more complex picture than that found in any other part of the body accessible to endoscopy. The bronchoscope is a speculum; its rigid structure and size and the anatomic design of the tracheobronchial tree restrict the extent of the air passages that are accessible to inspection. Employing the standard bronchoscope, only the trachea, larger bronchi, and some major orifices to different lobes are visible. The small segmental bronchi and peripheral radicles cannot be seen. However, telescopic inserts with different lens systems, introduced through the bronchoscope, permit inspection of otherwise hidden portions of the bronchial tree. These attachments have greatly increased the scope of inspection and permit direct examination of segmental orifices and divisions. In spite of this, some portions still remain beyond our vision. However, these areas are amenable to an indirect method of examination by the collection of secretions from segmental bronchi for bacteriologic and cytologic studies. This material should be collected from the precise subdivision leading to the disease. The examiner must therefore be thoroughly conversant with the segmental anatomy and internal topography of the tracheobronchial tree and should be accustomed to interpreting chest x-rays with respect to segmental distribution of disease. No examination of the bronchial tree is adequate by present-day standards unless the telescopic inserts are employed.

Bronchial bleeding demands bronchoscopy just as unexplained rectal bleeding demands proctoscopy. Adequate topical anesthesia is essential for successful bronchoscopy, and a

routine method of examination must be developed. There are special features which are important. One should determine whether the major component of the lesion under vision is endobronchial, intrabronchial, or extrabronchial. Compression of a bronchus either on one side or in a circumferential manner so that it is concentrically narrowed, is an endoscopic sign of grave significance, usually denoting malignancy, and this same finding may also occur in Hodgkin's disease and in Boeck's sarcoidosis with marked lymphadenopathy.

A bronchoscopic diagnosis is made in one of three ways (1) visualization, (2) direct tissue biopsy, and (3) examination of secretions or lavage material aspirated from the site of the disease. Bronchoscopy, if properly performed, is acceptable to the patient under local anesthesia and can often be carried out as an outpatient examination. Early detection of bronchogenic cancer is essential, and bronchoscopy is indispensable to this end.

Esophagoscopy is the second endoscopic procedure used in the diagnosis of chest lesions. Many of the principles of bronchoscopy are directly applicable to the use of the esophagoscope. These are procedures requiring caution in their performance, as perforation of a bronchus or of the esophagus may result.

Examination of the Sputum

The sputum obtained from the productive cough is a mixture of transudate and exudate from the air-conducting system, and microscopic and bacteriologic studies are often rewarding. It is apparent that bacteriologic smears and culture will identify the offending pathogens responsible for many of the suppurative lung diseases. The identification of an organism gives the precise etiologic factor and, furthermore, cultural methods using the sensitivity-determining techniques will indicate the drug or chemotherapeutic agent of choice. The proof of tuberculosis rests on the identification of the tubercle bacillus in the sputum or bronchoscopic washings. Some uncommon forms of lung infections such as the fungus group may be identified by special cultural techniques.

Equally important is cytologic examination which permits the identification of malignant cells that have exfoliated from a cancer of the bronchial mucosa. Such microscopic examination requires a cytologist familiar with the appearances of malignant cells, who can interpret the slides accurately. Deep cough specimens are necessary for the examination in suspected cancer, and often direct bronchial washings will contain clumps of tumor cells. Clinics where competent cytologists are employed report an accuracy of 85% or better, false positives being rare.

Diagnostic Biopsy

Recently the cervicomediastinal node biopsy (scalene node biopsy) has proved to be of great value. The underlying anatomic fact is that the lymphatic drainage is to the deep cervical node chain on each side. The technique is a simple approach through a short incision above the clavicle. The deep cervical fascia is incised and the scalene fat pad exposed. This lies over the scalenus anticus muscle and invariably contains a group of small lymph nodes. Palpably enlarged nodes may be found and excised for section and identification. If enlarged nodes are not found, the scalene fat pad is removed for microscopic examination of its contained nodes. These nodes are often the mirror of the pathologic intrathoracic process and give an accurate tissue identification of any disease that may be present in the lungs or mediastinum. It is also possible to enter the superior mediastinum, in the paratracheal area, and palpate any gross tumor or lymph node enlargement in this region. If a node is palpated, a specimen may be obtained with a laryngeal biopsy forceps. It is possible to reach the level of the 6th rib posteriorly, and, on the right side, to feel the right upper lobe bronchus. Scalene node biopsy is valuable in diseases possessing an affinity for lymph nodes, such as Boeck's sarcoidosis, Hodgkin's disease, and other lymphomas, as well as cancer of the bronchus. Histoplasmosis, tuberculosis, some of the fungus diseases, and the pneumoconioses may also be diagnosed in this way. In addition to the tissue sections of the nodes, a portion of the freshly removed node

may be sent for bacteriologic culture. One other application is the submission of a portion of the biopsy specimen for mineral assay, to identify the pneumoconioses such as asbestosis and silicosis.

Its greatest use is in cancer of the lung, as often two facts are immediately established. In the first place, tissue diagnosis of metastatic carcinoma in the lymph node removed, and, second, this finding automatically contra-indicates any form of surgical intervention for excision of the primary neoplasm. A cervicomediastinal biopsy may be indicated even though no palpable enlargement of the lymph nodes is present, since they are situated beneath the deep cervical fascia and may not be easily palpated. In their series of cervicomediastinal biopsies, Harken and Black have demonstrated the usefulness of this procedure, as they obtained a positive diagnosis in 30% of cancer of the lung; they found that 40% yielded positive nodes in this area. In other words, 40% of the cases of carcinoma of the lung were at once proved to be inoperable. Therefore, in every case of this disease, either proved or suspected, a cervicomediastinal biopsy should be performed. Lesions of the right lung require only a right-sided biopsy, lesions of the left upper lobe require only a left-sided biopsy, but lesions of the left lower lobe, because of crossed lymphatic drainage, require a biopsy in both the supraclavicular areas before positive assessment can be obtained.

Direct lung biopsy has been advocated recently to establish the nature of certain intrathoracic diseases. This is a useful method to determine the identity of an obscure disease process and is generally used for lesions that are diffusely distributed through both lungs. Such conditions are found in Boeck's sarcoidosis, the pneumoconioses, peripheral bronchiolar carcinoma, obscure fibrotic diseases of the lung, and the Hammond-Rich syndrome. The biopsy is performed through a small thoracotomy incision in an anterior interspace. The patient in the supine position. An adequate representative wedge of tissue is removed from the edge of a lobe for histologic study. The cut lung edges are repaired, the lung is re-expanded, and the wound is closed.

From such a biopsy the exact identity of these bilateral pulmonary lesions is often revealed, whereas the x-ray appearance is not usually diagnostic. The operation is performed under endotracheal positive pressure anesthesia, requires a minimum of exposure, and has a low morbidity and mortality rate.

Aspiration biopsy is used only when all other methods of diagnosis have failed, and only for peripherally located lung tumors with adhesions or invasion of the chest wall or for some mediastinal masses.

Exploratory Thoracotomy

In a fair percentage of cases it is inevitable that despite a thorough investigation, an accurate diagnosis cannot be reached. Such cases require an exploratory thoracotomy, which is particularly applicable to the peripheral round lesion (coin lesion) in the lung. Actually, for such cases most of the aforementioned tests may be eliminated and a thoracotomy performed to approach the problem directly. This establishes its exact nature by excision and pathologic study and institutes definitive treatment at the time. Thoracotomy carries no greater risk than laparotomy and can be used for the same reasons.

In this category we should also mention the *idiopathic pleural effusion*. In spite of all methods of investigation, accurate diagnosis of some effusions is impossible, and there should be no hesitation in performing a thoracotomy to establish their identity and causative factor. These cases are prepared with antituberculosis drugs because a considerable percentage have a tuberculous basis. During exploratory thoracotomy, it is usually possible to obtain a section of tissue for immediate frozen section and diagnosis. If the lesion is located deeply within the parenchyma, a segmental wedge or lobe resection may be necessary.

CONGENITAL ANOMALIES OF THE THORACIC CAGE

Certain somewhat rare congenital anomalies of the thoracic structures or contents require recognition and, occasionally, operative correction.

Anomalies of Ribs and Pectus Excavatum ("Funnel Chest") (See Chapter 30.)

Hernia of Lung

Hernia of the lung may be congenital or acquired, due to trauma or infection involving some portion of the thorax. A true hernia exists when a portion of lung covered by parietal pleura protrudes through an abnormal opening in the thoracic wall, mediastinum, or diaphragm. *Prolapse* of lung is a protrusion of lung through the parietal pleura.

Etiology.—Most of the cases are traumatic, but rare congenital supraclavicular herniation through Sibson's fascia is encountered. Herniation may be due to large infected wounds of the chest.

Diagnosis.—The diagnosis is usually evident from the history and physical examination, there being a resilient, resonant tumor which appears on respiration, coughing, and straining.

Treatment.—Small supraclavicular hernias may be completely asymptomatic, and no operative treatment is indicated. Repair of Sibson's fascia can be performed in more severe cases. Repair of the traumatic types is more difficult, requiring frequently the use of fascia, periosteal flaps from adjacent ribs, and even the transplantation of ribs above and below the defect.

TRAUMA OF THE THORAX

Trauma of the thorax may involve injury not only to the structures of the chest wall but also to its contents. Several traumatic mechanisms are recognized, e.g., direct and indirect violence, blows, and blast injury. There may be a break in the continuity of the chest wall, including the pleura, e.g., stab and gunshot wounds, or there may be tears and ruptures of the intrathoracic organs, lungs, heart, pericardium, esophagus, and great vessels. Consequently, for the sake of clarity, this subject will be considered under the headings:

1. Nonpenetrating trauma of the thorax and viscera
2. Penetrating wounds of the thorax
3. Blast injuries of the thorax

Nonpenetrating Trauma of the Thorax and Viscera

This may result from direct blows as well as crushing injuries. *Contusions and hematomas* of the chest wall rarely require surgical treatment. *Rupture of an intercostal artery* from stab wounds or rib fractures, not penetrating the pleura, may occasionally require open exploration and ligation.

Fracture of Ribs

Etiology.—Direct blows, crushing injuries and, occasionally, muscular strain and severe coughing or sneezing may fracture the ribs. Pathologic conditions such as cysts or tumors predispose to fracture. The most common sites

pleura and lung, but the absence of this finding does not rule out lung damage. If the lung has been punctured, there may be bloody expectoration. Careful x-ray study will confirm the diagnosis.

Treatment.—The treatment of simple fractures involves some form of strapping, sedatives, and intercostal nerve block. *Strapping* can be done with adhesive tape, the conventional method of strapping the affected side to the unaffected side being most widely used. However, some find that complete circular strapping of the lower ribs is more effective, regardless of the site of fracture. A well-fitted and well-applied chest binder has been found to be just as effective and does not require

Fig. 222—A, Types of rib and chondral fractures B, Fracture displacement of sternum

are from the 4th-8th ribs, along the anterior and posterior axillary lines and at the angles. These usually result from compression of the chest. The 1st rib may be fractured in downward trauma to the clavicular region. Types vary from simple, undisplaced, to grossly comminuted fractures which may be complicated by damage to the deeper structures.

Signs and Symptoms.—Pain at the site of injury and on respiration is characteristic. Marked voluntary splinting of the abdominal muscles on the affected side is usual. Localized tenderness and crepitus may be felt at the site of fracture. Tissue emphysema is only present if there has been rupture of the parietal

shaving of the chest. It can be readjusted and removed for x-ray and physical examination of the chest.

Regional nerve block is useful in relieving severe pain and respiratory embarrassment early in the condition. One or usually two intercostal nerves are infiltrated with 1% Novocain above and below the site of fracture or fractures, 3-5 ml. being injected in each space.

Fracture and Dislocation of Costal Cartilages and Sternum

This is the result of either a direct blow or crushing injury. Injury to the intrathoracic

organs is quite common. Reduction of the dislocation may be necessary, with fixation by strapping or by hyperextension plaster mold. Open reduction and fixation by suture or Kirschner wire are occasionally necessary if gross displacement is present.

"Store-in-Chest"

This refers to a severe crushing injury when one side of the thorax has been driven in. Numerous ribs are usually fractured, frequently in two places (e.g., the axillary line and angles), plus fracture of the sternum and other bony parts. Serious complications such as tension pneumothorax, mediastinal emphysema, injury to major vessels, and mediastinal flutter, and later, empyema, lung abscess, and mediastinitis may result.

General supportive treatment such as oxygen, blood or plasma for shock, removal of bronchial secretions or blood is indicated.

Other complications will be discussed separately.

Penetrating Wounds of the Thorax

Penetrating wounds may be internal from comminuted fracture of ribs or external from stab and gunshot wounds. Intrathoracic complications result from injury to the lung, heart, and great vessels. Among the conditions that may be encountered, the following are the most important and will be discussed individually:

1. Collapse from massive hemorrhage
2. Tension pneumothorax, with or without hemothorax
3. Mediastinal emphysema
4. Pneumopericardium and hemopneumopericardium
5. Laceration or rupture of diaphragm, with injury to the abdominal organs and immediate or subsequent herniation into the thorax

Collapse From Massive Hemorrhage

This may be difficult to distinguish from primary traumatic shock. As a rule, collapse from shock is more rapid than that caused by hemorrhage, unless from some major source. In primary shock, the rapid weak pulse,

clammy skin, and low blood pressure are present immediately following injury.

Tension Pneumothorax and Hemothorax

These conditions result from any injury perforating the lung tissue when there is a nonadherent pleura. Comminuted rib fractures, with sharp spicules of bone driven into the lung, and stab and gunshot wounds are the most common causes. Tension pneumothorax is the term used to describe air in the pleural

Causes of pneumothorax (after Netter)

Types of pneumothorax

Fig 223.—Causes and types of pneumothorax

cavity under increasing pressure due to a "ball valve" wound of the lung or bronchus, when air leaks out during inspiration but cannot escape during expiration. In this way increasing positive pressure pneumothorax is built up, causing progressive collapse of the lung and mediastinal displacement. Blood or bloody fluid tends to collect in the pleural cavity, adding to the compression.

Symptoms and Signs.—The symptoms and signs are usually diagnostic. There may be subcutaneous emphysema as an indication of lung damage, dyspnea, frothy bloody sputum, cyanosis, rapid weak pulse, lowering of the blood pressure, and hyperresonance with absent breath sounds over the affected side. With accumulating blood or fluid there will be dullness at the base. There may also be evidence of mediastinal shift. All these symptoms and signs will become more acute if the condition is unrelieved, and the patient may go into general cardiorespiratory collapse and die.

In an emergency, this can be simply achieved by inserting a large needle, No. 18 or 16 gauge, through an intercostal space, and the air will be heard to escape under pressure. The needle is then attached to a pneumothorax apparatus, the pleural pressure measured, and further air removed until pressures approach normal. Positive pressures of 15-20 cm of water are often found.

If, after the removal of a significant amount of air (500-1,000 ml), the pleural pressure rises again, a more continuous form of pleural decompression is indicated. An intercostal

Fig 224.—Water-seal and suction drainage.

Diagnosis.—The diagnosis is made by the history and physical examination and confirmed by x-ray, if necessary, but in an acute stage this delay is not justified.

Treatment.—The treatment is to remove the air from the pleural cavity and restore mediastinal pressure relationships to normal.

catheter attached to a water-seal bottle or Wangenstein type of suction should be inserted. In this way positive pressure cannot recur, the opening in the lung will soon seal over, and the lung will be encouraged to expand, at which time the catheter is removed.

Traumatic Hemothorax

This may occur, with or without pneumothorax and from the same general causes as pneumothorax. Wounds of the major vessels such as the aorta, vena cava, or hilar vessels cause such exsanguinating hemorrhage that the actual hemothorax is of secondary importance. However, hemothorax as an established condition requires separate consideration.

Pathology.—The presence of a fairly large amount of sterile unclotted blood in the pleural cavity may be relatively asymptomatic unless it compresses the lung or causes enough mediastinal shift to produce respiratory or cardiac embarrassment. However, if allowed to remain in the pleural cavity, two complications may occur: organization and fibrothorax. These are caused by infection and clotting of the blood.

It has been well established that blood in the pleural cavity contaminated with bacteria or exudate from damaged tissues will clot, and soon layers of fibrin over the lung surface are formed. This leads to the condition of organized fibrothorax, where the lung is encased in a tough fibrous membrane which seriously impairs its respiratory function.

Diagnosis.—The diagnosis of small amounts of blood in the pleural cavity is difficult. Larger amounts give the characteristic signs of dullness and absent or distant breath sounds. X-ray shows the fluid level if a degree of pneumothorax is present as well.

Treatment.—Immediate aspiration of unclotted hemothorax is only indicated as an emergency measure to relieve respiratory distress, since increasing the negative pressure in the pleural cavity at this stage may only result in continued bleeding. However, in 24-48 hours, when conditions have likely become stabilized, aspiration can be started with safety, about 500 ml being removed daily or every other day until the pleural cavity is dry. Air should not be replaced, since the object is to keep the lung expanded. Penicillin 200,000-500,000 units in 5-10 ml of saline should be instilled at the end of the first aspiration and repeated if infection is suspected.

Clotted hemothorax may require rib resection and removal of clots, as in the open treatment of empyema. If the underlying lung

does not show a tendency to expand after removal of clots, a catheter should be left in the wound, or placed through a separate stab wound, and connected to negative suction, to encourage expansion of the lung. In the late case if the lung is encased in firm fibrous tissue and shows no ability to expand under positive pressure applied by the anesthetist, decortication should be undertaken. This is the peeling from the surface of the lung and visceral pleura of organized fibrous layers, thereby freeing the lung and permitting re-expansion. Fissures of the mediastinal and diaphragmatic surfaces should be freed as well.

Fig 225—Marked emphysema of face and neck, resulting from postpneumonecomy bronchial leak.

Mediastinal Emphysema

This may occur as a result of closed or open thoracic injuries, and is due to a tear in the mediastinal pleura. Straining, coughing, and concussion may also cause it. It is diagnosed occasionally by the presence of crepitation felt above the sternal notch extending into the neck and face and may be detected by x-ray. If sufficient pressure is produced, damming back of blood in the great veins occurs, and the patient expires from asphyxia.

The treatment is symptomatic and supportive unless localized pockets of air are demonstrated beneath the sternum, when aspiration often gives great relief.

Pneumopericardium and Pneumohemopericardium

These rare conditions result from lacerations of lung tissue close to the hilus, the air dissecting the fascial planes around the vessels and entering through a tear into the pericardial cavity. The heart shadow is enlarged by x-ray, and air may be demonstrated within the pericardium.

Laceration or Rupture of Diaphragm

Since the dome of the diaphragm rises to the level of the junction of the 4th or 5th rib with the sternum during expiration, the possibility of its being perforated during penetrating wounds of the chest must be considered when they occur below this level. Gunshot and shell fragments are responsible for many wounds of this type in warfare. The possibility of injury or perforation of abdominal organs must always be considered.

Pathology.—The possibilities of abdominal injury vary according to which side of the diaphragm has been penetrated. On the right side the liver covers its undersurface and prevents herniation of the intestines or other structures, and bleeding is usually not severe. On the left side, however, the stomach, colon, kidney, and spleen are all in close contact, and perforation of these organs usually gives rise to serious complications.

Diagnosis.—It is frequently quite difficult to determine whether penetration of the diaphragm and intra-abdominal organs has occurred in combination with wounds of the thorax. Abdominal splinting and rigidity may be present with thoracic injuries alone or may take several hours to appear from abdominal causes such as perforation of the colon. Perforation of the stomach is likely to cause early and acute splinting if the contents are spilled into the peritoneal cavity, also free air may be demonstrated by x-ray if perforation has occurred. However, in the presence of marked abdominal rigidity and rebound pain it is wiser to explore, since the mortality

from well-conducted early exploration is considerably less than that accompanied by late exploration when extensive peritonitis has developed.

Injury to the spleen presents the usual left-sided symptoms, and kidney damage accompanied by blood in the urine. Widespread extensive laceration of the left side of the diaphragm is present, herniation of viscera may take place immediately or at a later date and can be ascertained roentgenologically.

Treatment.—Surgical exploration of both thoracic and abdominal regions is usually indicated. The decision to explore through the chest and diaphragm depends greatly on the individual case.

In the face of serious thoracic wounds with extensive hemothorax, the transthoracic approach will, of course, be indicated in order to restore maximum pulmonary function. Later, exploration of the abdominal organs can be performed. With minor chest symptoms, such as from stab wounds, the abdominal route is usually indicated. Right-sided thoracoabdominal wounds are better approached through the thorax due to the anatomic relationship.

The most convenient double exposure can be obtained by entering the thorax through the 8th interspace and continuing the incision on to the abdomen as far as necessary. The rectus muscle can be retracted medially or sectioned as required. An adequate exposure of all the upper abdominal organs can be obtained in this way.

Open Wounds of Thorax

Etiology.—By open wounds, we mean those in which there exists an opening into the pleural cavity so large that the soft tissue cannot close it off, and there is free exchange of air through the opening. For this reason they are often referred to as sucking wounds. War wounds, shrapnel and shell fragments, severe automobile and industrial accidents are the common causes. Most stab and bullet wounds are not true sucking wounds, as the tissues of the chest wall seal the opening.

Pathology.—With one side of the thorax open to atmospheric pressure, several deleterious events occur to upset the normal cardio-respiratory physiology.

Collapse of lung on the affected side. With an unclosed opening in the pleura, and if there are no adhesions to support the lung, the collapse is usually complete, i.e., 50% of the respiratory capacity will be lost.

Mediastinal flutter. When one lung is collapsed, due to atmospheric pressure in the pleural cavity, the inspiratory pull of the thorax will be unbalanced, and the mediastinum, if mobile, will be drawn across to the good side during inspiration and return to the normal position during expiration. This continual shift of the mediastinum is called *mediastinal flutter* and is a large factor in the production of shock and respiratory embarrassment. It produces impaired function of the remaining lung and further tends to reduce the vital capacity.

Interference with cardiovascular function. Atmospheric pressure in the pleural cavity also impedes the return of blood to the heart by pressure on the vena cava and hilar vessels. Also, shift of the mediastinum occurring suddenly causes a kinking of the great vessels which may further contribute to respiratory distress.

Stagnation of air in the bronchial tree. Since the collapsed lung does not expand in unison with the good lung as in normal respiration, air tends to be sucked out of it during inspiration and forced back again during expiration. Thus there is a backward and forward shift of a certain amount of stale air in the bronchial tree.

Treatment.—Emergency treatment consists of immediate closure of the wound by tightly applied moist pads, a measure which in itself may produce marked improvement in the respiratory difficulty and general condition. Later care under proper conditions includes effective *débridement* of the wound under positive pressure anesthesia, control of bleeding vessels (intercostal), removal of foreign bodies or rib fragments, and repair of laceration of the lung. The chest wall is closed lightly, with negative suction drainage, after instilling penicillin and streptomycin into the pleural cavity. Tetanus antitoxin and polyvalent antigas bacillus antitoxin are given in accordance with routine surgical principles. The wound must be watched for evidence of infection in the muscle planes and reopened

if necessary. Hemothorax, tension pneumothorax, pneumonitis, lung abscess, and empyema must also be kept in mind as possible complications.

Some surgeons prefer to close the wound tightly and aspirate accumulated fluid and air, instilling penicillin and/or streptomycin with each aspiration. However, negative suction or water-seal drainage removes the fluid continuously and tends to keep the lung expanded; this is a definite advantage.

Blast Injuries of the Thorax

A blast explosion produces a momentary marked increase in air pressure immediately followed by a negative or suction wave. Injury may be sustained during both phases, but it is generally agreed that the initial pressure wave is the more destructive. The same principle acts in immersion blast, affecting, of course, only the immersed parts. The effect of bomb blast varies with the size of the missile and is most severe in the atomic bomb blast.

Pathology.—There is a sudden excessive increase in the intrapulmonary and mediastinal pressures. In the lungs, rupture of the vessels and alveoli fills the area with bloody exudate which seeps into the bronchi and is expectorated as a bloody, frothy sputum. The heart experiences a tamponading effect, squeezing the blood out of the thin-walled auricles into the pulmonary veins and vena cava.

Signs and Symptoms.—There may be a latent period before signs of shock, dyspnea, cough, and bloody expectoration begin. There may also be signs of an acute abdominal or cerebral condition. Atelectasis may be produced by retained secretions.

Treatment.—This consists of complete bed rest, efforts to clear the bronchial tree, and support of shock. Fluid and morphine should be given sparingly. Intranasal oxygen or an oxygen tent is helpful. Occasionally intrabronchial suction will be indicated. Wounds or injury to other systems, of course, should not be overlooked, and appropriate treatment should be given.

Death occurs from hemorrhage, respiratory insufficiency, cerebral injury, cardiac failure, and air embolism.

ACUTE PYOGENIC INFECTIONS OF PLEURA, LUNG, AND MEDIASTINUM

Empyema

Empyema is defined as pus in the pleural space (see also Chapter 30).

Etiology.—The incidence of empyema has markedly decreased since the widespread use of antibiotics in the pneumonias. The most common etiologic organisms are the pneumococcus, streptococcus, and staphylococcus. Other organisms found in mixed or putrid empy-

(5) via the blood stream as part of a septicemia; (6) infection of hemothorax due to any cause.

Pathology.—The pathology produced by an empyema depends on the infecting organism, the amount of effusion produced, and the site of the effusion. Mixed empyemas are far more toxic than those due to a single organism.

Anatomically, an empyema may be diffuse, i.e., involve the whole pleural cavity, or encysted, e.g., interlobar, diaphragmatic, mediastinal, apical, etc.

Fig 226.—Massive pneumococcal empyema treated by continuous suction drainage and later by rib resection and open drainage.
A, X-ray before drainage shows massive effusion with marked displacement of the mediastinum to the right.
B, Final result after drainage tube removed.

emas include Vincent's group, Friedlander's bacillus, *Esch coli*, and various anaerobic streptococci. The routes by which the pleural cavity may become infected are (1) from disease of the underlying lung, e.g., pneumonia of all types, lung abscess, bronchiectasis, infarction of the lung, (2) secondary to mediastinal infection, (3) introduction from outside, e.g., stab wound, pneumothorax, etc., (4) extension from a subdiaphragmatic abscess, liver abscess, or chest wall infection.

Empyema necessitatis indicates the relief of an empyema by spontaneous perforation of the chest wall.

The degree of respiratory embarrassment caused by an empyema depends largely on the amount of lung tissue collapsed by the fluid and the degree of mediastinal shift.

Signs and Symptoms.—Empyema usually follows a previously known pneumonia and is diagnosed by continuing fever, dyspnea,

dullness, absent breath sounds and voice sounds, and usually some tympany and egophony in the compressed lung above the pleural fluid.

Diagnosis.—The diagnosis of empyema, apart from the history and physical signs, is confirmed by aspiration and x-ray. Bacteriologic examination of the fluid removed should always be made, as well as notation of the physical characteristics of consistency, color, and odor.

Treatment.—The treatment of empyema has three aims. (1) to relieve the respiratory distress; (2) to reduce toxicity, (3) to pro-

drainage may be continuous or intermittent. *Continuous drainage* is performed by introducing an intercostal catheter into the empyema cavity and attaching it to a Wangensteen type of suction apparatus. In this way the fluid may be removed completely under controlled pressure and speed, forcing the lung to re-expand to fill the empyema space.

In general, the open method is indicated in all thick, purulent empyemas with localized margins and stable mediastinum, while the closed type of drainage is of value in early, massive watery effusions without localization or fixation of the mediastinum.

Fig. 227 -- Technique of rib resection and open drainage, for empyema

note re expansion of the collapsed lung and maintain it until adhesions have formed and obliterated the empyema cavity. These aims can be accomplished in a variety of ways, depending on the amount and type of fluid present. The various procedures are discussed under the heading of *open and closed drainage*.

Open drainage refers to a thoracotomy and the placing of a drainage tube directly into the empyema at its lowest level, thus producing open dependent drainage. *Closed*

Intermittent closed drainage is merely a periodic aspiration of fluid without air replacement, using a closed system. This procedure is usually combined with the instillation of a suitable antibiotic according to the bacterial flora. In a percentage of cases this form of treatment alone may abort or cure an early empyema. However, the late empyemas do not respond well to this form of treatment, and late re-infection and reaccumulation of pus, multiple loculation, and organizing fibrothorax are possible complications.

Chronic Empyema, Early and Late

Early chronic empyema may occur from 2-6 weeks after the effusion has become frankly purulent. It is characterized by organization of fibrin layers on the pleural surfaces, and of ordinary treatment in this stage may not bring about complete re-expansion of the lung. At this time, exploration of the thorax, decortication (or peeling off the fibrin layer from the visceral pleura) followed by continuous closed drainage will usually bring about complete re-expansion of the lung.

Late chronic empyema generally results from an improperly treated original empyema. Inadequate drainage, drainage too late in the disease, too early removal of tubes, retention of foreign bodies in the pleural cavity (tubes, gauze, sponges, etc.) and bronchopleural fistula are common causes. In these cases the degree of fibrosis is so marked that decortication is often impossible or too hazardous, and some other means of obliterating the cavity must be attempted. Saucerization of the cavity by removal of overlying ribs and thickened parietal pleura, as in the Schede type of thoracoplasty, is frequently indicated. The use of flap muscle grafts has been advocated to fill deeper cavities.

Lung Abscess

A lung abscess is a localized suppurative focus situated in the lung parenchyma, whereas gangrene of the lung is a more acute process with massive necrosis.

Etiology.—Acute lung abscess may be single or multiple and depends on a variety of etiologic factors

1. Acute pulmonary infections account for a large percentage of all lung abscesses, e.g. all types of pneumonia

2. Aspiration of septic material during operations on the mouth, nose, and throat, may aspiration of foreign bodies by children, may produce obstruction, atelectasis, and abscess.

3. Septic emboli in the bloodstream from other suppurative disease or septicemia, such as osteomyelitis or abdominal infection, may precipitate a lung abscess

4. Lung abscess may be a complication of other diseases, such as bronchiectasis or carcinoma of the lung.

5. Trauma of the lung occasionally results in abscess formation.

A wide bacterial flora is found in most lung abscesses and includes ordinary pyogenic organisms such as streptococci, staphylococci, pneumococci, Vincent's organisms, *H. m. influenzae*, colon bacilli, and numerous anaerobic organisms.

Pathology.—Usually two clinical types are recognized: the putrid and the nonputrid lung abscess. This classification really refers to the acuteness of the pathologic process responsible for the formation of the abscess as a result of the etiologic factors mentioned above. The segment of lung involved becomes atelectatic, and the alveoli are filled with serum and pus cells, and the parenchymal tissue is liquefied and destroyed. The blood vessels are thrombosed; this leads to further death of tissue, and a fan-shaped wedge of inflammation typically spreads out to involve the pleural surface and causes a pleuritis and obliteration of the pleural space over the area. Eventually the infective process may extend to involve the interlobar planes, mediastinal, or diaphragmatic surfaces.

During this phase there is a marked general reaction, and the condition is termed *acute*. This stage lasts from 4-6 weeks. Cavitation forms at this time due to expectoration of necrotic lung tissue through a bronchus. Non-necrotic lung tissue tends to localize, a firm fibrous ring is formed around it, toxicity lessens, and the state is described as *chronic*. Death may occur from overwhelming toxemia, or perforation into a free pleural cavity may produce a lethal infection of an unprepared pleura. The chronic stage may persist for months or years unless properly treated, producing clubbing of fingers and toes, low-grade devitalizing toxemia, and amyloid degeneration of the liver, spleen, and kidney.

Diagnosis.—The diagnosis is made on the basis of the clinical history and physical signs. The latter, however, may be extremely slight, as in the case of a deep-seated abscess. The sputum is usually characteristic and copious, 75-150 ml daily.

Localization by x-ray is easy, especially when the cavity contains air and fluid. Bronchography is usually not of much value in the diagnosis of lung abscess since Lipiodol rarely

Plate 12—Putrid Lung Abscess.

ADVANCED SAC
AND CYLINDR
BRONCHIECT.

Plate 13.—Marked Saccular Bronchiectasis.

Fig 228 —Hilar anatomy and technique of right pneumonectomy.

third decades of life. There is often a history of repeated attacks of pneumonia or of long-standing sinusitis. The earliest symptom is morning cough and expectoration. This gradually progresses until the patient may bring up several ounces of increasingly fetid sputum during the day. Clubbing of the fingers develops and constitutional symptoms of malaise, cachexia, loss of weight, and pleural pain now appear. Hemoptysis may occur from time to time and may be mistaken for the hemoptysis of tuberculosis. Life becomes a burden with incessant coughing of foul sputum. Fever, chills, and progressive emaciation lead, in the advanced untreated cases, to death during an acute flare-up. Amyloid degeneration is often seen.

Diagnosis.—The history including the diseases of childhood is important. The physical signs are those of impaired resonance at the bases, distinct breath sounds and showers of coarse, bubbling râles. Bronchography is necessary in outline the exact extent and clinical pattern of the condition. Bronchoscopy is usually performed. The blood picture is not characteristic but reflects the toxic and nutritional changes. Tests for amyloid disease may show abnormal retention of dye; the kidney function may be impaired.

Treatment.—In view of the underlying pathologic process, it is obvious that in well-established cases of bronchiectasis medical treatment is only palliative. However, it plays an important part in the preoperative preparation. Postural drainage, bronchoscopic aspiration, high-caloric and high-vitamin diet will improve the general condition. Autogenous vaccines are of value in certain cases. The antibiotics have been a great factor in the treatment of bronchiectasis. Aerosol penicillin and streptomycin will reduce the sputum in many cases and, carried on postoperatively, lessen the incidence of postoperative pneumonia and empyema.

Lobectomy, segmental resection, and pneumonectomy, as indicated in the individual case, offer the only hope of a permanent cure. These operations, in capable hands, now carry a mortality rate as low as that in any other branch of major surgery. Many thoracic clinics are reporting consecutive series of 100 or more lobectomies without a fatality.

The modern technique of this operation is well standardized, the individual ligation of the pulmonary arteries, pulmonary veins, and bronchi being performed at the site of resection. Endotracheal anesthesia is most commonly used.

The posterolateral approach, resecting the 7th or 8th rib, is used for lower lobe lobectomy, and this or the anterior approach between the 3rd and 4th ribs in front for pneumonectomy. Negative suction drainage is generally employed for 24-48 hours postoperatively to remove the serosanguineous effusion and to encourage the remaining lobe or lobes to expand.

Complications.—The complications which may follow lobectomy are (1) early—hemorrhage from a major vessel, shock, atelectasis and postoperative pneumonitis, embolism, and pulmonary thrombosis, and (2) late—bronchopleural fistula, empyema, and wound infection. Rigid attention to operative technique and careful postoperative handling will eliminate many of the complications.

THE SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS

Introduction

This aspect of thoracic surgery originated at the beginning of the present century. For many years progress was slow and erratic, the end results uncertain and discouraging. Finally, the operation of thoracoplasty became firmly established and was responsible for the arrest of many cases of active tuberculosis. In the past 10 years the surgical resection of a tuberculous focus in the lung has become, in most instances, the operation of choice. The future outlook for the complete control of this disease by public health measures is encouraging, but the need for detection and medical and surgical therapy will continue for many years. Tuberculosis will probably remain endemic in our population indefinitely, although there is now less cause for the great fear that has existed in the past. With modern diagnostic aids, medical management, antituberculosis drugs, and surgical procedures, one can expect an excellent chance of cure within a reasonable period of time. Furthermore, the ravages of this disease, exemplified

by some of the tuberculous derelicts in sanitariums, will eventually disappear. Tuberculosis need not reach the stage of total lung destruction and disseminated disease

General Considerations

A number of factors have been responsible for the improvement in management and treatment in recent years. Undoubtedly, the most important development has been the discovery of antimicrobial drugs which are effective against the tubercle bacillus and which control and localize the infection. Streptomycin, the first practical antituberculosis drug, was discovered by Shatz and Waksman in 1944. Para-aminosalicylic acid (PAS) was introduced in 1946 and is usually used in combination with streptomycin or some of the drugs discovered later. Its greatest advantage is that it can delay or prevent drug resistance by the tubercle bacillus. In 1952 isoniazidic acid hydrazide (isoniazid or INH) was found to be effective against the tubercle bacillus, and this has proved to be a very useful drug. Several other drugs have appeared since the discovery of isoniazid, such as viomycin (1951) and pyrazinamide (1952), but all have either toxic or other unfavorable properties which complicate their use.

Treatment with these drugs combined with bed rest and other supportive measures prepares the patient for surgery if his disease process will not heal by medical therapy alone. The antituberculosis drugs localize the main focus of disease, control or eliminate satellite areas of involvement, minimize the amount of pulmonary parenchyma involved, clear the zone around the main focus of exudative reaction, reduce the magnitude of the operation, and preserve a greater percentage of functioning pulmonary tissue.

Pulmonary tuberculosis almost invariably begins as a focal area of disease. Extension may occur from this starting point either by direct invasion or more generally by way of bronchogenic spread. The initial disease should be controlled and confined by the antituberculosis drugs to as small an area as possible. The destructive changes caused by the original infection can be surgically treated when the primary infection has been controlled. Un-

questionably, the antituberculosis drugs have been largely responsible for the marked reduction in mortality and morbidity following resection for this disease and for the increased percentage of sputum-negative cases following surgery.

Many of these patients chronically debilitated by tuberculosis present disturbances in electrolyte balance and in blood volume; such persons require correction in the preoperative and postoperative periods. Likewise adrenal insufficiency may occur, requiring replacement therapy.

It is necessary to stress the importance of the anesthetist plays in the surgery of tuberculosis, as he is not only responsible for the controlled narcosis and relaxation of the patient but must also be expert in replacement therapy and in the maintenance of vital functions and must understand the pharmacologic action of the different agents employed. During the operative procedure he must prevent the contamination of other portions of the same or opposite lung by the spread of tubercle bacilli which occurs when the cough reflex is absent. In this respect, the technique of blocking the bronchus to a diseased lung, lobe, or segment is now a prerequisite for administration of an anesthetic in the presence of tuberculous suppurative disease. This is accomplished by using special blockers that are positioned to exclude the bronchus leading to the diseased site or by introducing special catheters so that the inflated balloon effectively seals and confines the secretions to the diseased area to be removed. Very often the anesthetist is called upon to block an entire lung and carry the patient through a major operation on the other lung. At the conclusion of the operation the patient should be conscious and possess an active cough reflex which expels contaminated secretions from the airway and prevents postoperative atelectasis.

The critical assessment of the functional capacity or reserve of the lungs is particularly important in cases of extensive disease. It is necessary to know the amount each lung is contributing to the over-all breathing capacity of the patient. It would be impractical to remove a lung or a lobe and leave the patient so short of breath that normal activity is

seriously restricted. The respiratory physiologist has become an indispensable part of the team for the assessment of these cases. With this knowledge, poor-risk patients with markedly diminished function may be accepted, as many difficulties can be circumvented or alleviated by special measures.

Improved surgical techniques and understanding of the segmental distribution of disease have enabled resections to be confined to the actual site of the disease, thus preserving a maximum amount of normal lung tissue. Complete familiarity with the chest and its mechanics and physiology and the increase in the understanding of cardiovascular lesions and their management have decreased the operative risk markedly in the past few years. Recently there have been newer techniques developed for the collapse therapy of this disease, which have received additional impetus from the use of synthetic materials inserted to provide direct, localized collapse with preservation of maximum pulmonary function.

Pathology

The position of surgery in the treatment of this disease is based on an understanding of the pathologic processes involved. Tuberculosis must always be considered a *systemic* disease in which we recognize and treat certain local lesions that manifest themselves by becoming clinically demonstrable. It follows that the general care of the patient remains fundamental. Surgery is used to assist the healing process or to extirpate disease which cannot be controlled by conservative therapy. Since it must be considered a systemic disease, the recognition of extrapulmonary foci, such as bone and renal tuberculosis, tuberculous meningitis, and miliary tuberculosis, is important.

The profession is indebted to Medlar, the pathologist, who elucidated the different patterns of pulmonary tuberculosis and established the pathologic concepts on which modern treatment is based.

In the lung, tuberculosis invariably begins as a localized area of consolidation, i.e., *tuberculous pneumonitis*. This may be manifested only as a slight chest cold or may simulate a severe toxic pneumonia. The lesion may be so small as to be missed on chest

x-rays, or it may show varying degrees of severity up to complete consolidation of a lobe or a diffuse bronchopneumonia. A tuberculous infection having started as a pneumonitis may terminate in three ways: (1) complete resolution of the pneumonia may occur, leaving no residual x-ray evidence; (2) a more severe infection in a patient with natural resistance may show slow healing with residual scar formation leaving the so-called spot on the lung, or (3) a still more severe infection may result in local death of tissue, associated with the particular type of inflammatory reaction and pus formation which are characteristic of tuberculosis. This is designated *caseous necrosis* and results in the formation of a chronic tuberculous abscess.

The student can easily appreciate that surgical treatment is not concerned with the first two sequelae quoted above. These are healed by the patient's natural resistance, in some cases without treatment and without his awareness of the disease. Many cases with the aid of medical treatment are brought to a state of permanent scar formation and quiescence. Caseation necrosis, persisting or progressing to cavity formation or to solid areas containing tuberculous pus, becomes a surgical problem.

A tuberculous abscess in the lung is of a chronic nature. The contents vary from semisolid to liquid, and the wall is composed of tuberculous granulations which mature slowly into scar tissue. The very nature of the pathologic process involved in the formation of these cavities often results in mechanical problems in healing and so may require a surgical solution. Similar to nonspecific lung abscesses situated near the surface, there is an overlying area of pleuritis which leads to local obliteration of the pleural space by adhesions. The semisolid contents of the cavity may liquefy, gradually erode, and point into an adjacent bronchus and be evacuated by coughing. At this point the patient produces contaminated sputum for the first time and becomes a so-called *open case of tuberculosis*. Sputum examination at this stage will reveal the presence of tubercle bacilli. During this time, heavy contamination may lead to bronchogenic spread to other parts of the same or opposite lung. This spreading may occur by means of cough propulsion, by gravity flow

during sleep, or during periods of severe debility. The closed tuberculous lesion containing liquid or inspissated pus, which appears on x-ray as a completely opaque well-circumscribed shadow, is known as a *tuberculoma*. When such a lesion empties into a bronchus, it becomes partially or completely evacuated, air enters the area previously occupied by the pus, and the presence of a cavity is then easily demonstrable. If air and pus are present in the same cavity, there will be an air-fluid level in the upright position, visible on x-ray. If it is completely evacuated, an air-filled cavity will be noted. A cavity is never stationary, and if the bronchial communication remains open and the walls have not become rigid, the cavity wall moves as the patient breathes. The actual method of healing of cavities is not settled, but for practical purposes, healing occurs only when the space becomes filled and obliterated with granulations. This in turn becomes scar and the walls approximate and fuse, obliterating the infected surface and preventing the continued growth of organisms.

Another factor of importance is the state of the bronchus. *Tuberculous bronchitis* influences the fate of every cavity. The small bronchus which drains the cavity is inevitably involved in the infection. Tuberculous endobronchial disease heals slowly with scar production. The scar contracts, and stenosis develops which may progress to complete bronchial obstruction resulting in atelectasis and failure of drainage of the involved lung. This stenosis may involve segmental, lobar, or main bronchi. If complete obstruction of a draining bronchus does occur, there is no exit for the accumulated caseous material, and a serious chronic condition is created. The failure to recognize active endobronchial tuberculous disease may result in failure of a resection due to the development of a *bronchial fistula*. It is difficult to sever an infected bronchus, suture it, and expect it to heal by primary intention. Many of the bronchial fistulas following resection can be attributed to unrecognized bronchial disease.

It must be realized that all three types of reaction commonly coexist in the same patient, one or more areas of caseation necrosis being

surrounded by zones of fibrosis and exudative reaction. Such areas may clear considerably or completely with medical treatment. Many open positive cavities may persist, but no tubercle bacilli can be found in the sputum despite diligent search. These *open negative* cases require resection, since examination and culture of the cavity wall and contents have usually revealed large numbers of *tubercle bacilli*.

These pathologic changes can be modified and sometimes cleared completely by the administration of antituberculosis drugs. Under their influence pneumonic areas can resolve, tuberculous ulcers in bronchi disappear, and cavities may even heal soundly. In the most advanced lesions, the infective element may be brought under control or even abolished, but the structural defects of the infection remain. Larger cavities persist either open or filled with caseous material, bronchi remain stenosed by scar tissue, and bronchiectasis persists. Such irreversible changes are a constant source of future reactivation and spread of the disease. When this state is reached and the patient's condition is satisfactory, resection is the logical step to remove the major focus of disease.

Surgical Treatment

The function of surgery in the treatment of pulmonary tuberculosis is to create by mechanical means a situation that encourages healing or to remove diseased areas that are damaged beyond repair. Surgical treatment should be deferred until the disease process has been stabilized by medical means and has remained so for a reasonable period. Recently it has been realized that this may be safely performed at an earlier stage with good results. However, this is a matter of judgment, and treatment must be adapted to the individual case.

General Considerations

The proper preparation of the surgical patient is important to prevent serious complications. The following general measures apply to all cases.

1. Systemic measures
2. Local measures
3. Specific measures

Systemic Measures.—The general nutritional state is important. The blood picture should be checked for hemoglobin content, hematocrit, red cell determinations, and NPN. Blood studies should also include the glucose levels, as diabetes and tuberculosis frequently coexist. Determination of the blood volume is important, especially in the debilitated or poor-risk patient. This will serve as a baseline for the control of blood loss and replacement throughout the procedure and in the postoperative phase and will assist greatly in avoiding overtransfusion which is equally as serious as undertransfusion. The electrolytes must be checked regularly when indicated and a stable state of water balance maintained. Antituberculosis drugs should be administered in proper doses and after sensitivity tests. Vitamin therapy is indicated in most cases. The psychologic preparation for the operation and postoperative phase is an accessory measure. Many centers have trained psychiatrists for such purposes. In the postoperative phase, rehabilitation programs and occupational therapy will speed recovery.

Local Measures.—These consist mainly of treatment designed to decrease the amount of sputum, to increase the efficiency of breathing, and to eliminate any obstructive factor in the minor bronchi. Bronchodilators may be administered to decrease the congestion in the mucosa, eliminate bronchospasm, and provide better aeration and drainage for exudative and cavitary disease. Postural drainage, suitable for the location of the cavity, is instituted to render the patient as dry as possible before operation. Secondary infecting organisms in the sputum should be cultured, tested for sensitivity, and controlled by suitable antibiotics. The patient should discontinue smoking for 2-3 weeks prior to surgery, to diminish bronchospasm and cough. An adequate preparation of the operative site is necessary to minimize the tendency to wound infection.

Specific Measures.—These include the localization of the major focus of disease by the different x-ray techniques, namely, by plain x-rays in different projections, tomography, and bronchography. Cardiac assessment is obtained if the patient's symptoms and signs so warrant or if he is in the older age group.

Pulmonary function studies are necessary in planning the type and extent of resection and help to prognosticate the result. Prior to resection and every collapse procedure, each patient should have a detailed bronchoscopic examination. Finally, trained physiotherapists should visit the patient preoperatively, to explain that certain muscles are to be cut and to instruct the patient in shoulder girdle movements and in breathing exercises, emphasizing the use of the diaphragm and chest wall. This program continued in the postoperative period reduces the incidence of atelectasis and the failure of expansion, diminishes residual spaces, and minimizes the resultant deformity. An efficient recovery room is desirable for proper postoperative management.

Surgical Procedures

The operations may be grouped into three categories:

1. Drainage operations
2. Collapse or relaxing operations
3. Resection operations

Drainage Operations.—The larger cavities fail to heal because of the mechanical factors present, such as a thick-walled cavity or a bronchial stenosis. Monaldi, an Italian surgeon, popularized a method whereby a catheter was inserted through the chest wall into the cavity which was decompressed by continuous suction. This operation proved unsatisfactory and today is little used. *Empyema complicating pulmonary tuberculosis may require drainage.* This may be accomplished either by the closed water-seal or open methods; and such procedures may be supplemented later by decortication. This procedure removes the thick, external peel on the surface of the lung and lining of the chest wall and allows the underlying lung to expand, become adherent, and thus obliterate the space.

Collapse or Relaxing Operations.—In order to circumvent some of the mechanical factors preventing closure of a cavity, methods have been devised to promote approximation of its walls. *Artificial pneumothorax* is the introduction of air into the pleural space to negate the normal intrapleural pressures and provide concentric collapse of the lung. How-

ever, this is little used today. Likewise, artificial pneumoperitoneum has been largely abandoned.

Crush and avulsion of the phrenic nerve, used extensively in the past, is rarely employed. When the phrenic nerve is crushed, recovery from paralysis usually occurs in a period of 4-6 months, although a certain percentage of patients never regain function of the nerve. Complete avulsion of the nerve is no longer practiced. Even simple crushing should be discouraged, because permanent paralysis of the

a thoracoscope, which permits collapse of the lung. This operation along with artificial pneumothorax has become obsolete.

Extrapleural pneumonolysis was designed to produce a selective collapse over the desired area by dissection outside the parietal pleura, to create a space between the inner aspect of the endothoracic fascia and the outer aspect of the parietal pleura. Once the space is created by surgical dissection, it is then maintained by introducing artificial materials such as fat, paraffin wax, paraffin oil,

Fig. 229.—Decortication specimen which formed complete cast of pleural space in a case of chronic pleural effusion due to tuberculosis.
A, External surface showing imprints of ribs
B, Opened specimen showing shaggy fibrous wall after fluid was evacuated

diaphragm deprives the patient of respiratory function which may be required later, particularly if his disease becomes bilateral.

Intrapleural pneumonolysis is used in conjunction with artificial pneumothorax where adhesions between the visceral pleura and the chest wall prevent adequate collapse. The adhesions are cut by a cautery introduced through

and various synthetic materials. The use of such materials for this purpose is known as *plombage*. Air may be introduced under positive pressure into this surgically created space and is known as *extrapleural pneumothorax*. Complications caused by the presence of a foreign body and the difficulties of maintaining the space limit the field of this operation.

Extrapariosteal or extrafascial pneumonolysis with plombage is a method of collapse therapy which involves stripping the periosteum and muscle from the ribs over the required area, so that the soft tissues of the chest wall, including the costal periosteum, collapse inward, depressing the underlying lung. The denuded ribs are not resected, and a packing or plomb is introduced to occupy the space between the ribs and collapsed soft tissues, to maintain the collapse. Regenerated ribs eventually form from the displaced periosteum in the collapsed position. The original ribs may be resected later and the packing removed, or if the packing is inert, it and the original ribs may be left in place. As in the extrapleural plombage, the material employed may be the same, but the newer synthetic materials are preferable. Lucite spheres were popular a few years ago and are still in use. However, some of the newer synthetic spongelike materials, such as Ivalon, seem to be the best agents for these procedures. Special indications for this operation exist where the disease process is limited to the apex of the lung in patients with low pulmonary reserve and where bilateral cavitory disease is present with reduced respiratory function. Contraindications include large peripheral cavities, marked fibrosis at the apex, densely adherent lung at the periphery, and cavities located below the apex. This procedure offers particular advantages. It produces a localized selective collapse, there is a retention of maximal function of normal lung tissue, there is minimal deformity of the chest wall, maximal preservation of chest wall motion without paradoxical movement, and the advantage of a one-stage operation. Complications may occur, such as infection of the extrapariosteal space by tuberculous and nontuberculous organisms, especially in the presence of the foreign body. Bronchopleural fistula and secondary hemorrhage may occur. When used in selected cases, this operation will provide a high percentage (85%) of arrested cases.

For many years, thoracoplasty of various types was the mainstay in the surgical treatment of pulmonary tuberculosis. Since 1950, thoracoplasty has been virtually abandoned in favor of excisional therapy. Thoracoplasty implies the permanent collapse of a portion

of the chest wall by removal of part of the ribs. The resection of the ribs is subperiosteal, leaving the detached periosteum on the collapsed soft tissue outside of the lung and parietal pleura. This periosteum will eventually regenerate irregular, bony plates in the position of deformity, thus establishing a permanent and irreversible collapse. The amount of collapse varies with the extent of the disease and the number of ribs resected. Usually at least 5 ribs must be resected to obtain useful collapse. However, the number may vary from a maximum of 11 ribs down to 6 or 7 as the average. Extensive rib resection results in instability of the affected portion of the chest wall, which reduces the efficiency of respiration because of the resultant paradoxical movement. It interferes in part with the effectiveness of cough, and for these reasons the operation must be performed in two stages so that the degree of paradoxical interference with cough efficiency is as great as to endanger the patient's condition. The usual 6- or 7-rib thoracoplasty is generally accomplished in two stages, resecting 3 or 4 ribs at the first, and the remainder at the second operation. The interval between the procedures must be sufficient to allow stabilization by healing fibrosis of the chest wall from the preceding operation but not so long as to permit rib regeneration which would restore the chest wall and prevent additional collapse following the next stage. It is usually allowed to allow two weeks, with a maximum interval of three weeks between stages. It is important to remove the entire posterior portion of the ribs and the transverse processes. Failure to do this leaves a residual deformity beside the bodies of the vertebrae, and the transverse processes. Here, a cavity may remain open without complete collapse and result in *thoracoplasty failure*. A refinement to aid the collapse is a procedure known as *apicolysis* which may be added to the thoracoplasty. During the first stage, the upper ribs have been resected, the lower portion of the lung is freed by dissection in the extrapleural or the extrafascial plane, and is displaced downward toward the hilum. The principle of combining apicolysis with thoracoplasty to enhance the concentric collapse

TABLE 18
COLLECTED MORTALITY STATISTICS

SURGEON OR INSTITUTION	YEAR REPORTED	NUMBER OF RESECTIONS			MORTALITY
		STREPTOMYCIN COVERAGE NOT STATED	WITHOUT STREPTOMYCIN COVERAGE	WITH STREPTOMYCIN COVERAGE	
Sweet (Boston)	1946	63			33.0%
Barley (Philadelphia)	1947	80			27.5%
Gale (Madison)	1949	80			2.5%
Jones (Los Angeles)	1950		35	88	28.6% 5.7%
Day, Tuttle, O'Brien (Detroit)	1950			202	6.9%
Munz (Cleveland)	1950			53 consecutive	7.5%
Overholt (Boston)	1952		224	184	10.9% 3.9%
Royal Edward Laurentian Hospital, Montreal	1957			400 consecutive	1.5%

toward the hilum was first advocated by Semb and is widely practiced.

Bilateral tuberculosis may be treated by bilateral thoracoplasty; however, operations of this magnitude may produce a marked reduction in respiratory reserve. Before excisional operations and antituberculosis drugs were employed, a sputum conversion rate of 70-80% and a mortality rate of 2-5% were considered satisfactory.

Thoracoplasty, however, is not indicated for the treatment of solid lesions which cannot be collapsed, tuberculous bronchiectasis, atelectatic lobes, or diseased segments distal to stenosed bronchi. Giant cavities may be closed by thoracoplasty, but not infrequently they are merely reduced in size and still contain tubercle bacilli. Thick-walled cavities may be merely displaced without evidence of closure. Thoracoplasty is wasteful of functioning lung tissue, since it compresses not only the cavity but also adjacent normal tissue. In cases of thoracoplasty for bilateral disease, the resultant loss of healthy lung tissue is poorly tolerated. The inevitable deformity resulting from thoracoplasty and the necessity for multiple operations are other objections to this form of treatment. Thoracoplasty still has a limited use in the treatment of tuberculosis but in the majority of cases has been replaced by newer techniques.

Resection Operations.—In spite of isolated successful attempts to remove tuberculous segments of the lung (Tuffier, 1891; Lowson, 1893), resection operations were not generally adopted because of the excessive morbidity and mortality. Consequently, the safer collapse procedures were employed for many years. Recently, with the discovery of antituberculosis drugs and the improvement of surgical techniques, resection therapy has become the method of choice. The early mortality rate was 25-30%, whereas recent series report a rate of 3% or less (See Table 18.)

Resection surgery includes segmentectomy or wedge resection, lobectomy, and total pneumonectomy if indicated. A unilateral or bilateral combination of lobes or segments may be removed.

Preparation and Assessment for Resection

These patients require preoperative assessment and preparation. The essentials are as follows:

- 1 General measures, including bed rest, nutrition, elimination of secondary infection, and improvement of breathing function by physiotherapy.
- 2 Uninterrupted treatment with antituberculosis drugs in adequate dosage, for a minimum of three months.
- 3 Bronchoscopy is essential. The condition of the bronchial tree and particularly the condition of the mucosa at the proposed line of resection are carefully assessed.
- 4 Preoperative study of pulmonary function is required in patients with far advanced or bilateral disease.

5. Vital functions such as cardiovascular, renal, and adrenal must be assessed. Reduction in the amount of sputum by the use of postural drainage and bronchodilators in aerosol form is indicated.

6. Patients with low pulmonary function may require preoperative or postoperative tracheostomy and/or artificial ventilation.

The indications for resection in pulmonary tuberculosis are still controversial. Absolute and relative indications are as follows:

Absolute Indications

- 1 Destroyed lung
- 2 Destroyed lobe
- 3 Thoracoplasty failure
- 4 Bronchostenosis
- 5 Bronchiectasis
- 6 Thick-walled cavities
- 7 Multiple cavities
- 8 Lower lobe cavities
- 9 Tuberculoma
- 10 Residual open cavities

Relative Indications

- 1 Multiple solid foci which are anatomically suitable for resection
- 2 Undetermined lesions where neoplasm cannot be excluded
- 3 Encysted chronic tuberculous empyema
- 4 Bilateral disease (with adequate pulmonary function)

The operation may be performed with the patient in the supine, prone, or lateral position. The advantage of the *prone position* is that secretions do not gravitate into other parts of the same or opposite lung. The *supine position* is preferred by some but fails to give as good exposure. The *lateral position* with a posterolateral or an anterolateral incision is generally used. Two venous infusions should be started for forced transfusion of blood if required.

The technique of the operation varies and will not be discussed. Adequate postoperative drainage must be instituted to remove accumulated air, blood, and serum. This is usually accomplished with two chest tubes, one anterior and one posterior, connected to a water-seal drainage or to a suction apparatus.

The postoperative care includes (1) determination and recording of blood pressure, pulse, and respiration, (2) administration of oxygen if required, (3) physiotherapy to encourage respiratory and shoulder girdle movements; (4) sedatives adequate to provide

relief of pain but not to interfere with the cough mechanism; (5) maintenance of the patency of the drainage tubes; (6) administration of antibiotics for tuberculous and pyogenic organisms; (7) care for the bladder and bowel function and gastrointestinal distention; (8) early ambulation.

Convalescence is generally rapid and the patient is usually sitting on the edge of the bed on the 2nd or 3rd day, out of bed on the 3rd or 4th day, and walking and able to go to the bathroom by the 5th day. The skin sutures are removed on the 7th or 8th day, and by this time the lungs should be completely expanded.

As a rule, in the case of minimal disease, a period of three months of antituberculous drug therapy after operation is sufficient, but when there is a fair amount of nodular palpable disease, a minimum of six months is preferable. In cases in which bilateral disease is present, uninterrupted drug therapy should be continued until the second side is operated upon or until the disease is in a state of permanent control.

The complications fall into two groups:

General Complications:

- 1 Hemorrhage
- 2 Shock
- 3 CO₂ retention (respiratory acidosis)
- 4 Hyperventilation (respiratory alkalosis)
- 5 Gastrointestinal distention and paresis
- 6 Wound infection
- 7 Bladder infection

Specific Complications:

- 1 Spread of disease
- 2 Atelectasis
- 3 Hemothorax
- 4 Pneumonia
- 5 Bronchial fistula
- 6 Persistent air leak
- 7 Residual space
- 8 Empyema (tuberculous, pyogenic, or mixed)

Hemorrhage and shock are prevented by adequate estimation of the blood loss and its replacement throughout the procedure. *CO₂ retention* must be anticipated and should be recognized if the typical picture presents. However, this is an uncommon complication, as is also *respiratory alkalosis* from hyperventilation. *Gastrointestinal distention* following chest operations occurs frequently but is generally not as pronounced or prolonged as that

following abdominal operations. *Acute gastric dilatation* requires immediate decompression. *Wound infections* should be minimal. *Bladder infections* may occur, particularly if the patient requires catheterization

To avoid *atelectasis*, particular attention must be paid to the adequate maintenance

of the airways and the encouragement of coughing. Endotracheal suction and bronchoscopy should be employed without hesitation, if an atelectasis persists. In severe exsanguinating internal hemorrhage, it must be suspected that a ligature has slipped from, or cut through, a major vessel. The patient must be

 D, Scar, 10 days postoperatively.

immediately returned to the operating room, the wound opened, and the bleeding point identified and controlled. In delayed hemothorax, repeated aspirations and the use of enzymatic digestion may be employed. If this is not successful and the lung fails to expand because of the formation of fibrous adhesions, decortication may be necessary.

The *postoperative spread of tuberculosis* should be prevented by adequate preoperative preparation and postoperative management. If it occurs, intensive antibiotic treatment and local measures to ensure adequate evacuation of secretions will usually secure resolution. A *nontuberculous pneumonia* may develop during the postoperative phase and is handled in the usual manner.

Fistula of a main bronchus is a complication and early recognition is necessary. If discovered early the patient is returned to the operating room and the leak located and resutured. Delayed or unrecognized fistulas may be complicated by empyema and are best treated by closed catheter drainage until the acute phase is over. Then some method of eradicating the fistula and empyema space must be undertaken. A *persistent air leak* from a small peripheral bronchus or bronchiole is a troublesome complication following segmental resection. If closure does not occur spontaneously, it is advisable to locate and suture the leak or apply a muscle or flap graft to the opening. At the same time it may be necessary to perform a localized thoracoplasty or plombage to eradicate the residual space. *Tuberculous empyema* is treated by closed catheter drainage in the early phase, followed by later open drainage and thoracoplasty, and/or decortication, if indicated.

The common postoperative complications in a series of cases are listed below

Complications of Resection Surgery

- 1 Progression of pulmonary disease
 - A Early—bronchopneumonia, tuberculous, nontuberculous, or mixed
 - B Late—reactivation of latent or presumably stable disease
- 2 Bronchial fistula
 - A Early—due to inadequate closure or failure to obtain primary healing
 - B Late—due to late ulceration of bronchial stump, generally a sequela of endobronchial tuberculosis

3. Empyema
 - A. Early—may be tuberculous, nontuberculous, or mixed
 - B. Late—due to latent infection or progression of pleural tuberculosis
- 4 Miscellaneous
 - Immediate, early, and late following resection
 - a. Exsanguinating hemorrhage
 - b Shock—mild to severe
 - c. Airway obstruction
 - d Cardiac—arrest, arrhythmia, or failure
 - e Atelectasis
 - f. Wound infection
 - g Paralytic ileus or acute gastric dilatation
 - h Persistent pleural effusion
 - i Persistent air leak and residual air space

The complications of persistent air leak and residual air space occur particularly after segmental resections and may require secondary operative procedures

Results and Prognosis

The immediate mortality rate following resection for pulmonary tuberculosis should be in the neighborhood of 3-5%. Permanent sputum conversion should occur in 85% or more. Negative reports of direct smear and culture from three direct sputum specimens, three gastric washings, and three laryngeal swabs, carried out over a period of one year postoperatively, are desirable as proof of permanent sputum conversion.

Complete patient rehabilitation should be about 75%. Approximately 15% of the remainder are rehabilitated to part-time work, leaving less than 10% who, although sputum-negative and able to carry on ordinary activities, are not able to earn their livelihood. The relapse rate is uncertain. Late deaths have occurred and are frequently attributed to causes other than active pulmonary tuberculosis. It is possible that in some cases of total lung removal, late deaths may be due to the development of right heart failure subsequent to removal of one lung and the existence of healed fibrosed disease in the other. It would appear that resection for pulmonary tuberculosis is, in most cases, the operation of choice. Its aims are (1) permanent arrest of the disease, (2) preservation of maximum pulmonary function, (3) elimination of residual postoperative deformity, (4) economy of time and expense to the patient, and (5) complete and full rehabilitation to an enjoyable and productive existence.

INTRATHORACIC CYSTS AND TUMORS

Cysts and Tumors of the Pleura

Cysts of the pleura are so rare that they have no practical significance.

Tumors of the pleura may arise from the secreting membrane itself (endotheliomas) or from the subserous layer. The latter are sarcomatous.

It may be difficult to differentiate tumors arising in the periphery of the lung from those of the pleura and chest wall. Pneumothorax may be of value. Bloody pleural effusion usually accompanies malignant tumors of the pleura. Tumor cells may be found on examination of the sediment. Metastatic involvement of the pleura is common.

Mediastinal Cysts and Tumors

Mediastinal cysts and tumors are frequently discovered by survey films and may be asymptomatic. Symptoms are usually caused by pressure on other mediastinal structures, viz., great vessels, esophagus, and nerves. The following classification, modified from Bradford, indicates the wide etiologic range.

- I. *Congenital cysts*
 1. Dermoid
 2. Teratomas
 3. Pericardial cysts
 4. Bronchial cysts
 5. Gastric and esophageal cysts
 6. Cystic lymphangioma
- II. *Acquired cysts*
 1. Parasitic
 2. Neoplastic
 3. Cystic hematoma
- III. *Connective tissue tumors*
 1. Fibroma
 2. Lipoma
 3. Leiomyoma
 4. Chondroma, chondrosarcoma
 5. Sarcoma
- IV. *Neurogenic tumors*
 1. Neurofibroma
 2. Ganglioneuroma
 3. Neuroblastoma
- V. *Thymic tumors*
 1. Benign thymoma
 2. Malignant thymoma
 3. Thymic cysts

VI. Primary tumors of lymph nodes

1. Lymphosarcoma
2. Hodgkin's
3. Sarcoidosis

VII. Primary and secondary sarcoma

VIII. Primary and secondary carcinoma

IX. Intrathoracic goiter

X. Aneurysm

The signs and symptoms of mediastinal cysts and tumors vary greatly with the etiology, and many are discovered accidentally during routine chest films. However, large tumors or cysts produce congestion of neck veins, substernal pain, dyspnea, dysphagia, cough, hoarseness, and Horner's syndrome from pressure on the trachea, esophagus, great vessels, and nerves, respectively.

The diagnosis may be extremely difficult and only decided at thoracotomy and exploration. X-rays in various diameters, barium swallow, and pneumothorax assist in localizing the tumor. Fluoroscopy, kymography, bronchoscopy, and bronchography give added information in appropriate cases.

Venography and angiocardiology have been advocated recently as a distinct aid in diagnosis, particularly of aneurysms of the aorta or great vessels. Therapeutic x-ray therapy is useful in differentiating lymphosarcoma, which shrinks considerably following this treatment, from benign tumors and cysts which remain unchanged in size.

Treatment.—It is generally agreed that all mediastinal tumors and cysts should be removed surgically if there are no serious contraindications. Many of the benign tumors and cysts undergo malignant changes in later years. Perforation of an infected cyst into a bronchus adds bronchiectasis or lung abscess to the existing condition, and many require lobectomy or pneumonectomy as well.

Anterior mediastinal tumors are exposed by the anterior approach through the appropriate interspace, dividing the costal cartilage above and below. Occasionally, splitting of the sternum vertically and laterally into the 2nd or 3rd interspace is necessary to expose an anterior mediastinal tumor such as thymoma.

Posterior mediastinal tumors are reached by the posterolateral approach.

Tumors and Cysts of the Lung

Cysts of the Lung

Cysts of the lung are relatively rare but are being found with increasing frequency, due to wider use of the x-ray. They may be *congenital or acquired*

Congenital Cysts.—

(1) Dermoid cysts and teratomas of the lung are reported but are extremely rare. (2) Simple cysts containing air and lined by various types of epithelium are the most common. There is considerable controversy as to the origin of these cysts, but they may be solitary, bilateral, or multiple. The multiple type may be associated with bronchiectasis or honeycomb lung

Signs, Symptoms, and Diagnosis.—Many cysts remain asymptomatic for years. Infection or rupture with spontaneous pneumothorax may cause the initial symptoms. With large multiple cysts, increasing respiratory distress is inevitable

The diagnosis is made by the history and x-rays of the chest. Lipiodol will only occasionally enter a cyst, since the communication with the bronchi may be extremely minute or tortuous

Treatment.—Removal of the solitary cyst by dissection is feasible in some cases. The bronchial communications may be difficult to close. Lobectomy or segmental resection can be performed in certain cases

Acute pneumothorax may be a recurring symptom and is treated by suction drainage maintained for 2-3 weeks if necessary. A mild empyema if it results may cause adhesions and prevent subsequent ruptures

Acquired Cysts.—

Acquired cysts are believed to follow lung infection, pneumonia, and pneumonitis and are not to be confused with cavitation of lung abscess, bronchiectasis, or cancer

Emphysematous bullae or blebs are lung cysts without any epithelial lining and can present the same clinical picture as the true lung cyst.

Benign Tumors of the Lung

Histologically benign tumors are found in about 2% of the total cases of tumors of the bronchial tree. Fibroma, lipoma, adenoma,

chondroma, and hamartoma are some of the benign tumors occasionally reported. However, these tumors may undergo malignant change or cause bronchial obstruction with the sequelae of atelectasis, pneumonitis, lung abscess, and bronchiectasis.

Diagnosis.—Diagnosis of many of these tumors can be made by bronchoscopy and biopsy as they tend to originate in the large bronchi

Treatment.—Local removal by the bronchoscope is only rarely advisable, and lobectomy or pneumonectomy is generally performed, especially if infection of the lung has occurred distally.

Bronchogenic Carcinoma

Incidence.—Cancer of the lung is now the commonest visceral cancer in the male population of the United States, where it causes more deaths than any other malignant tumor. Approximately 85% of cases occur in men. It is responsible for approximately 1 in 18 of all male deaths. Today the death rate has more than doubled that of 10 years ago and each year continues to show an increase, as evidenced by clinical investigations, vital statistics, and autopsy records. The incidence is 2-3 times higher in urban than in rural areas, but the relative increase is the same. In females, although the death rate is still comparatively low, the incidence shows a definite rise. The rate of increase among males is $2\frac{1}{2}$ times as great as that in females.

Etiology.—The exact etiology of carcinoma of the lung is not definitely established, but certain theories have recently been advanced which indicate that chronic irritants such as cigarette smoke and industrial pollution may be causative factors

Tobacco Smoking.—During the past 18 years, 16 independent studies in five geographically separate countries have shown that there is a statistical association between smoking and the occurrence of lung cancer. In Britain, investigations in progress for more than five years resulted in the following definite conclusions endorsed by the Medical Research Council with regard to lung cancer in men

Fig 231—Bronchial adenoma of left lower stem bronchus causing obstructive bronchiectasis pneumonia

Plate 14.—Advanced Bronchogenic Carcinoma With Partial Obstruction of the Right Main Stem Bronchus and Metastatic Spread.

1. There is a higher mortality in
 - (a) smokers than in nonsmokers (5-15 times)
 - (b) heavy than in light smokers
 - (c) cigarette than in pipe smokers
 - (d) those who continued to smoke than in those who gave it up

2. Heavy smokers had a death rate of more than 40 times that of nonsmokers

3. The current death rate for lung cancer is approximately 1 in 8 for smokers and 1 in 300 for nonsmokers

4. Men who cease to smoke in their early 40's may reduce the likelihood of developing the disease by at least one half

Experimentally, five known carcinogenic substances have been extracted from tobacco smoke which consist largely of microscopic oily droplets held in suspension in the air. The droplets are of such size that they may be taken into the lung tissues and retained there. However, these carcinogenic agents are present in tobacco smoke in such small amounts that there is some doubt that they could be an etiologic factor. Some workers have succeeded in producing tumors in animals by painting concentrated tobacco tar extracts on the skin.

Atmospheric Pollution—Lung cancer is greater in urban than in rural districts. Carcinogenic substances have been identified in coal and industrial smoke and automobile fumes, and therefore it has been postulated and supported by investigation that atmospheric pollution may be a cause of the increase in lung cancer. Nonsmokers in cities have a definitely higher death rate from lung cancer than those in rural areas. In comparison with cigarette smoking it seems likely that atmospheric pollution plays a minor part in causing this disease.

Pathologic Considerations—There are three cell types of bronchogenic carcinoma:

1. Squamous cell carcinoma
2. Adenocarcinoma
3. Anaplastic or undifferentiated carcinoma
 - (a) large cell carcinoma
 - (b) small cell (oat cell) carcinoma

The commonest type encountered is the squamous cell and its anaplastic variant which comprise 80-85% of the whole group, adenocarcinoma constituting the remainder

Alveolar cell carcinoma is an unusual type. In the past, the site of origin has been considered the lining of the alveolar sacs. At present, the evidence favors its origin from the terminal bronchiolar epithelium. For this reason it is now called *peripheral bronchiolar carcinoma*.

All lung cancers arise from the bronchial mucosa. The site in the bronchial tree determines whether the lesion will be centrally or peripherally placed. The tumor may project into the lumen as a polypoid mass, infiltrate the submucosa, or grow extrabronchially. The two latter types produce narrowing or occlusion by either circumferential invasion or extrinsic pressure on the wall by involved lymph nodes. The commonest sites are at the points of bronchial division.

These cancers spread by direct extension, by the lymphatic channels, and by the blood stream. *Involvement of the lymph channels and nodes* is usually the first sign of extension beyond the primary growth. This metastatic process permeates centrally toward the hilum and thence along the previously described routes of lymphatic drainage to the deep cervical nodes. The pleural space drainage is to the anterior and posterior intercostal nodes and to the paravertebral nodes beneath the crura of the diaphragm.

Direct invasion of the chest wall, the diaphragm, the heart, and other mediastinal structures may occur. Involvement of the phrenic nerve results in paralysis of the diaphragm and that of the recurrent laryngeal nerve, in vocal cord paralysis. Direct infiltration of the pleura produces a pleural effusion, which may be sanguineous and reveal exfoliated malignant cells on cytologic examination. When direct extension occurs at the apex, it produces a group of symptoms known as *Pancoast syndrome*, consisting of Horner's syndrome, shoulder girdle and arm pain, and the presence of an apical mass on x-ray examination.

Some authorities believe that definite correlation exists between cell type and prognosis. Squamous cell types carry the best prognosis, with adenocarcinoma in second place. Of the anaplastic group the large cell has a better prognosis than the small cell type.

Symptoms and Diagnosis.—The essential points in the diagnosis of a case of broncho-

Fig 233—Unresolved pneumonia due to proved bronchogenic carcinoma, male patient 35 years
 A, X-ray showing pneumonic area involving posterior segment of right lower lobe. Cough, chills, and fever present
 B, Persistence of shadow 10 days later despite adequate antibiotic and local measures
 C, Bronchoscopic findings
 D, Resected right lung, medial view, with main bronchi opened. Note small raised growth obstructing posterior basal bronchus U.L., Upper lobe bronchus, M.L., middle lobe bronchus
 E, Injected specimen, medial view, demonstrating obstruction of the corresponding segmental bronchus with distal consolidation.

genic carcinoma have been outlined on pages 441-445. Early diagnosis, which implies a time factor, is essential. Patients who present symptoms of only 2-3 weeks' duration may have widespread metastases from a small primary carcinoma. Others may be treated for weeks or months for virus or atypical pneumonia or possibly pulmonary tuberculosis. Failure of a pneumonic infiltration to clear completely when treated adequately by drug therapy should arouse the suspicion that some mechanical factor may be responsible. A pneumonic process that fails to resolve under medical treatment promptly (3 weeks) should be submitted to intensive investigation, to exclude a *neoplastic* basis.

The symptoms are as follows: *Cough* is present in the majority of cases; either it is a new symptom, or there is a change in the character or severity of the patient's "smoker's cough." *Hemoptysis* is a serious symptom and sign, the history and significance of which should be carefully investigated. *Chest pain*, pleuritic in type, indicates pleural involvement or a pleuritis secondary to an obstructive pneumonitis. Severe constant chest pain is caused by invasion of the chest wall and ribs. *Febrile episodes* typical of pneumonitis are common and may be the first indication that such a lesion is present. *Pneumonias* in men, especially in heavy smokers over the age of 45, should be regarded with suspicion. *Unilateral wheezing*, *hoarseness*, the sudden appearance of *osteoarthritis* and *neuropathies*, and *shortness of breath* may also focus the attention on this tumor. *Weight loss* is not reliable as a sign of lung cancer.

Investigative procedures should be repeated in suspicious cases which are difficult to diagnose.

Assessment and Management.—Once a diagnosis of bronchogenic carcinoma has been confirmed by histologic studies, the proper management and treatment are important. Of all cases of bronchogenic carcinoma on first observation, one third show evidence of metastases, one third prove to be unresectable on exploratory thoracotomy, and one third are resectable. Surgical removal of the affected lung is the best and only means of effective treatment.

It is possible by careful analysis of the findings to predict unresectability accurately, sparing many patients an exploratory operation. Three investigations are helpful. First, by *x-ray*, particularly tomography, extensive lymph node involvement may be definitely established. Spread into adjacent structures such as the esophagus contraindicates resection. Rib involvement may be demonstrated but does not necessarily preclude resection. Generally, paralysis of the diaphragm or of a vocal cord, indicating nerve involvement, signifies inoperability. Second, *bronchoscopy* may reveal signs of inoperability, such as extensive tracheal invasion, involvement of both mainstem bronchi, fixation of the carina or its distortion by involved subcarinal nodes. Compression stenosis of a lobar bronchus indicates extensive lymph node encroachment. Resection would be doubtful where this finding is present, particularly in respect to the right upper lobe bronchus. Third, the procedure of *scalene node* and *fat pad biopsy* will often reveal involvement by tumor, contraindicating thoracotomy. On the other hand, a negative biopsy is a favorable finding, necessitating a thoracotomy.

By using the above methods it is possible to increase the resection rate from 30-60%. Follow-up studies indicate that the prognosis in this highly selected group is much better than in the series reported to date which did not receive such preoperative investigation.

A patient should not be denied the benefit of a thoracotomy unless there is unequivocal pathologic evidence that the tumor is inoperable. Many cases in spite of assessment will present a doubtful chance of resectability, nevertheless these should be explored.

Those patients in whom resection has been proved impossible, by investigation or thoracotomy, should receive palliative therapy, which includes a course of radiation or chemical therapy with drugs such as nitrogen mustard. Both these methods of treatment may give temporary improvement, but they do not cure the underlying neoplastic process.

The Peripheral Round Nodule.—The asymptomatic peripheral round shadow, discovered accidentally by routine x-ray, presents a diagnostic problem. These nodules may be congenital, parasitic, inflammatory, or neo-

plastic in origin. Statistics show a malignant process in 30-40% of these cases. Investigation is limited to minimal essential points. The radiologic presence of calcium in such a lesion is no longer regarded as a positive sign of a benign process. Thoracotomy, biopsy of the mass by wedge resection, segmental resection, or lobectomy is indicated. The histologic identity of the mass is established by frozen section and dictates the course of treatment.

Surgical Treatment

The surgical treatment of bronchogenic carcinoma is total pneumonectomy with *en bloc* mediastinal lymph node dissection where possible. Lobectomy may be indicated when the carcinoma is peripherally situated. Preparation and management for operation are similar to that outlined in the section on tuberculosis, bearing in mind the general principles of all cancer surgery.

Survival Rate

As total pneumonectomy has only been performed for this disease in recent years, survival statistics have been reported for a correspondingly short period.

Many series have been reported where the 5-year survival rate following resection has ranged from 20-30%. One series reports a 5-year survival rate of 42.9% in patients with localized growths as compared with 6.2% for those with extension. The asymptomatic, localized, peripheral round lesions present a 5-year survival of 76%. In the symptomatic peripheral lesions, however, the survival rate after resection drops to 36%.

The time of survival of the untreated patient is seldom longer than 12-18 months. On the other hand, it has become apparent that a patient who survives pneumonectomy for 2 years has an excellent chance of living for 5 years, i.e., the 2- and 5-year survival rates approximate closely, few deaths after 2 years being caused by persistence or recurrence of the tumor.

Chapter 16

Cardiac Surgery

Arthur M. Vineberg, M.D., and David R. Murphy, MD

INTRODUCTION

Since the origin of the human race, the human heart has been the target of enemy weapons. Today it is the subject of the surgeon's scalpel. The possibility that a wounded heart could heal appears to have been discounted until Carrolanus described two patients in whom heart wounds did heal, with recovery. This fact was confirmed by Block in 1882 and by Del Vecchio in 1894, who successfully sutured wounds in the hearts of rabbits and dogs, respectively. This was immediately followed by a successful repair of a human right ventricle by Rehn in 1896.

During the past 15 years innumerable congenital and acquired lesions of the pericardium and great vessels of the heart have been corrected, with low mortality and excellent results. In the past three years development of the extracorporeal circulation, through the pump oxygenator, has enabled the surgeon to open individual heart chambers and repair congenital defects and correct acquired lesions. Recently, through induced cardiac arrest, human hearts have been stopped and successfully restarted. The arrested dry heart affords the opportunity to operate on intracardiac and mural defects with unhurried ease and accuracy.

PREOPERATIVE AND POSTOPERATIVE MANAGEMENT

Diagnostic Methods

In the evaluation of patients with congenital or acquired heart disease, specialized diagnostic methods may be of great assistance.

In fact, preoperative diagnosis is often impossible without some of these studies superimposed on a complete history and thorough physical examination.

X-ray and Fluoroscopy

Careful radiologic examination is of great importance. The cardiac chambers, great vessels, and any abnormal vascular contours can be evaluated and calcific deposits in the valves and pericardium detected.

Angiography

In general, the technique is to opacify the circulation by injecting a radiopaque medium and to follow its course by serial x-rays taken very rapidly. Recently, image-intensifying screens have been used to take motion pictures of the circulation.

Venous Angiocardiography.—In this test the dye is injected into a peripheral vein and its course followed through the heart and great vessels.

Selective Angiocardiography.—The lesion may be outlined more selectively by injecting the medium through a cardiac catheter placed near the suspected area.

Aortography.—A thin catheter is threaded through a systemic artery into the aortic arch and the dye injected. This will show the thoracic aorta and has been used to delineate the coronary arteries. (See Fig. 211.)

Arterial Oxygen Saturation

Arterial blood is analyzed to determine its oxygen content per 100 ml. This figure is

compared with the oxygen content of the same blood when fully saturated (oxygen capacity) to give the *oxygen saturation*. Normal arterial oxygen saturation is 94-99%. Arterial blood below 94% is termed *unsaturated*, although it may not be evident clinically as cyanosis.

Cardiac Catheterization

Cardiac catheterization involves the passage of a catheter through a systemic vein into the vena cava and through the right atrium and ventricle into the pulmonary artery. Blood samples are taken and pressure recordings made as the catheter is withdrawn through the right heart chambers. A rise in oxygen saturation of the right heart blood indicates entrance of blood from the left heart. This *left-to-right shunt* may occur at the interatrial, interventricular, or arterial level. The pressure determinations may show abnormal gradients across the tricuspid or pulmonary valves, indicating stenosis or insufficiency, and they may also demonstrate pulmonary hypertension.

Physiologic data on lesions of the aortic and mitral valves may be obtained by left heart catheterization via the left atrium or left ventricle. The left atrium is entered by a needle introduced through the chest wall or through a bronchoscope. A catheter is then threaded through the needle into the chambers of the left heart and into the aorta. As the catheter is withdrawn, measurements are made of the pressures and of the gradients across the valves. Similar observations can be made by direct percutaneous needle puncture of the left ventricle.

Dye Curves

Dye curves may be of great aid in the diagnosis of intracardiac or aortic-pulmonary shunts. The technique involves the injection of a dye such as T-1824 (Evans blue) through a cardiac catheter into the right side of the heart and the subsequent plotting of dye concentration in serial samples removed from a systemic artery. The same information may be obtained by the use of a photoelectric cell attached to the ear lobe.

The dye curves are altered by a right-to-left or a left-to-right shunt. A right-to-left shunt shows an early appearance time and

often a double-peaked curve, one peak produced by the dye that has passed through the defect and one by that which has taken the normal route. The site of the right-to-left shunt can be determined by making dye injections at different points on the right side of the heart. Only those injections proximal to the shunt will give the characteristic curve. Left-to-right shunts have a normal appearance time, but the peak is lower than normal, and the disappearance time is prolonged due to the recirculation of dye through the shunt.

Fig 234.—A, Dye curve showing right-to-left shunt, demonstrating early appearance time as compared to normal.

B, Dye curve showing left-to-right shunt, demonstrating prolonged disappearance time.

(Courtesy The Montreal Children's Hospital)

Electrocardiogram

Multiple lead electrocardiographic studies at rest and after exercise are of great importance and help in detecting individual chamber enlargement, dilatation and/or hypertrophy, as well as the presence of myocardial ischemia or infarction.

Exercise Test

The Masters' two-step test and treadmill give objective evidence of exercise tolerance.

Preoperative Preparation

This must include not only the *careful* and *accurate* establishment of the diagnosis but also detailed investigations to detect other disease, which in itself may be incurable or

Cardiac Surgery

Arthur M. Vineberg, M.D., and David R. Murphy, M.D.

INTRODUCTION

Since the origin of the human race, the human heart has been the target of enemy weapons. Today it is the subject of the surgeon's scalpel. The possibility that a wounded heart could heal appears to have been discounted until Carrolanus described two patients in whom heart wounds did heal, with recovery. This fact was confirmed by Block in 1882 and by Del Vecchio in 1894, who successfully sutured wounds in the hearts of rabbits and dogs, respectively. This was immediately followed by a successful repair of a human right ventricle by Rehn in 1896.

During the past 15 years innumerable congenital and acquired lesions of the pericardium and great vessels of the heart have been corrected, with low mortality and excellent results. In the past three years development of the extracorporeal circulation, through the pump oxygenator, has enabled the surgeon to open individual heart chambers and repair congenital defects and correct acquired lesions. Recently, through induced cardiac arrest, human hearts have been stopped and successfully restarted. The arrested dry heart affords the opportunity to operate on intracardiac and mural defects with unhurried ease and accuracy.

PREOPERATIVE AND POSTOPERATIVE MANAGEMENT

Diagnostic Methods

In the evaluation of patients with congenital or acquired heart disease, specialized diagnostic methods may be of great assistance.

In fact, preoperative diagnosis is often impossible without some of these studies superimposed on a complete history and thorough physical examination.

X-ray and Fluoroscopy

Careful radiologic examination is of great importance. The cardiac chambers, great vessels, and any abnormal vascular contours can be evaluated and calcific deposits in the valves and pericardium detected.

Angiography

In general, the technique is to opacify the circulation by injecting a radiopaque medium and to follow its course by serial x-rays taken very rapidly. Recently, image-intensifying screens have been used to take motion pictures of the circulation.

Venous Angiocardiography.—In this test the dye is injected into a peripheral vein and its course followed through the heart and great vessels.

Selective Angiocardiography.—The lesion may be outlined more selectively by injecting the medium through a cardiac catheter placed near the suspected area.

Aortography.—A thin catheter is threaded through a systemic artery into the aortic arch and the dye injected. This will show the thoracic aorta and has been used to delineate the coronary arteries. (See Fig. 241.)

Arterial Oxygen Saturation

Arterial blood is analyzed to determine its oxygen content per 100 ml. This figure is

compared with the oxygen content of the umbilical blood when fully saturated (oxygen capacity) to give the *oxygen saturation*. Normal arterial oxygen saturation is 94-99%. Arterial blood below 91% is termed *unsaturated*, although it may not be evident clinically as cyanosis.

Cardiac Catheterization

Cardiac catheterization involves the passage of a catheter through a systemic vein into the vena cava and through the right atrium and ventricle into the pulmonary artery. Blood samples are taken and pressure recordings made as the catheter is withdrawn through the right heart chambers. A rise in oxygen saturation of the right heart blood indicates entrance of blood from the left heart. This *left-to-right shunt* may occur at the interatrial, interventricular, or arterial level. The pressure determinations may show abnormal gradients across the tricuspid or pulmonary valves, indicating stenosis or insufficiency, and they may also demonstrate pulmonary hypertension.

Physiologic data on lesions of the aortic and mitral valves may be obtained by left heart catheterization via the left atrium or left ventricle. The left atrium is entered by a needle introduced through the chest wall or through a bronchoscope. A catheter is then threaded through the needle into the chambers of the left heart and into the aorta. As the catheter is withdrawn, measurements are made of the pressures and of the gradients across the valves. Similar observations can be made by direct percutaneous needle puncture of the left ventricle.

Dye Curves

Dye curves may be of great aid in the diagnosis of intracardiac or aortic-pulmonary shunts. The technique involves the injection of a dye such as T-1824 (Evans blue) through a cardiac catheter into the right side of the heart and the subsequent plotting of dye concentration in serial samples removed from a systemic artery. The same information may be obtained by the use of a photoelectric cell attached to the ear lobe.

The dye curves are altered by a right-to-left or a left-to-right shunt. A right-to-left shunt shows an early appearance time and

often a double-peaked curve, one peak produced by the dye that has passed through the defect and one by that which has taken the normal route. The site of the right-to-left shunt can be determined by making dye injections at different points on the right side of the heart. Only those injections proximal to the shunt will give the characteristic curve. Left-to-right shunts have a normal appearance time, but the peak is lower than normal, and the disappearance time is prolonged due to the recirculation of dye through the shunt.

Electrocardiogram

Multiple lead electrocardiographic studies at rest and after exercise are of great importance and help in detecting individual chamber enlargement, dilatation and/or hypertrophy, as well as the presence of myocardial ischemia or infarction.

Exercise Test

The Masters' two-step test and treadmill give objective evidence of exercise tolerance.

Preoperative Preparation

This must include not only the *careful* and *accurate* establishment of the diagnosis but also detailed investigations to detect other disease, which in itself may be incurable or

alter the results of cardiac surgery. Long-standing heart disease may affect many organs which must be fully evaluated.

Preoperative Controls.—Certain studies aid greatly in postoperative management.

1 Daily records of pulse and blood pressure set a base line for maintenance during and after operation.

2. A record of daily fluid intake and output shows the effectiveness of control of heart failure and forms a basis for postoperative fluid administration. Changes in the patient's weight from day to day will confirm this.

3 Blood electrolytes should be estimated, particularly in patients with heart failure who have been treated by diuretics and low-salt diet.

4. A coagulogram may reveal altered prothrombin activity due to liver changes caused by venous congestion or hypotension.

5. Total and fractional blood volumes should be measured. Elevated blood volumes markedly increase the hazards of cardiac surgery. Alterations from the normal should therefore be corrected when possible before operation.

Control of Heart Failure.—Heart failure, whether of the right or left ventricle, must be controlled preoperatively. The *wet patient* is a poor operative risk. Satisfactory correction of heart failure is clinically manifested when the patient can sleep in the horizontal position without distress.

Search for Foci of Infection.—Foci of infection, particularly in the mouth and skin, must be noted and treated.

Carotid Artery Compression.—With the patient lying down, the carotids above the carotid sinus are compressed until he becomes dizzy, and this is repeated daily until tolerance is at least 5 minutes.

Psychologic Factors.—Any patient who submits to an operation is worried and anxious, even if this state is not noticeable. All personnel must work to reassure the patient. Careful sedation, avoiding hypotension and hypoxia, is helpful. It is of particular importance to avoid a nerve-racking wait in the operating room while the anesthetist prepares his drugs, and a terrifying jumble of impressions and medical words drifts into the patient's sedated brain. The patient with valvular

disease may go into failure; the patient with coronary artery disease may suffer infarction.

Postoperative Care

The care of the postoperative heart patient presents two facets: (1) the care of a thoracotomy, requiring rapid re-expansion of the lungs, and (2) the treatment of the cardiovascular system.

Nursing Care

This involves the following in addition to routine care:

1. Frequent regular recording of blood pressure and heart rate, both apical and radial.

2. Maintenance of blood pressure where necessary by regulation of rate of continuously administered intravenous vasopressors.

3. Massage of chest drainage tube or tubes every half hour to avoid blockage by clotting, and watching for excessive blood loss through the drainage tube.

4. Maintenance of Wangensteen drainage of stomach when used.

5. Administration of oxygen and assistance of patient with deep-breathing exercises, throat aspiration, and coughing.

6. Movement of patient from side to side; early movement and gentle massage of legs.

Medical Care

Postoperative heart patients should be returned to a recovery room where they are kept until the anesthetic staff and medical surgical team agree that they are fit for return to the ward. The quantity of fluid to be administered and the level at which blood pressure should be maintained are based upon preoperative blood pressure and fluid balance observations. Sedatives and cardiac drugs such as digitalis are given intramuscularly. For patients in whom maintenance of blood pressure is difficult, a blood volume study may reveal need for transfusion. All orders should be clearly written and the nurses' duties carefully explained.

In general, the first six hours following operations for acquired valvular disease or closed heart procedures for congenital defects present no more difficulties than pulmonary operations.

Patients who have undergone major surgery for coronary artery heart disease or who have had treatment for congenital cardiac lesions, using the pump oxygenator, require maintenance in the supine position, without turning, for much longer periods, as early movement frequently causes sudden hypotension and cardiac irregularities.

Consalescent Care

Despite surgical correction of a congenital or valvular defect, the heart does not become normal immediately. Weeks and sometimes months are needed for the heart to readjust itself. The same is true for coronary heart disease. Rest and supportive measures may be necessary for a considerable period of time.

MANAGEMENT IN THE OPERATING ROOM

It is wise to anesthetize the patient in a pre-op room rather than in the operating room. Precautions to maintain blood pressure during induction must be taken. Once the patient is anesthetized, at least three intravenous entries should be started to ensure rapid delivery of blood if necessary. In coronary artery patients the maintenance of blood pressure during the entire procedure and in the postoperative period is so essential that an intravenous cannula or catheter is tied into a vein in the leg or arm.

A cardioscope and electrocardiogram are connected to the patient so that the character of the heart contractions is visible at all times. In poor-risk patients who have had preoperative cerebral emboli, and in cases where the pump oxygenator is used, continuous recording of brain waves by the EEG machine indicates the efficiency of the circulation.

Cerebral anoxia is quickly reflected in the EEG and in most instances can be rapidly remedied. The efficiency of cardiac massage when cardiac arrest occurs, of pulmonary ventilation, bilateral carotid compression, and of the pump oxygenator is shown by the EEG tracing. A photocell oximeter attached to the patient's ear lobe acts as another monitor of oxygen saturation.

Pressure recording apparatus is used for measurement of intracardiac pressures. Continuous recording of intra-arterial pressure is helpful in aortic valve and open heart surgery. Multipanel electronic pressure recorders are useful for this purpose. Open heart surgery requires facilities for rapid determination of pH, CO_2 , and hemolysis.

Blood Loss.—Because of the narrow range of safety in fluid balance, estimation of blood loss is essential. A reasonably accurate method is the weighing of blood-soaked sponges (gravimetric method). Techniques for continuous measurement of blood volume are still experimental.

CARDIAC ARREST

Definition.—Cardiac arrest means cessation of effective heartbeat due to cardiac asystole or ventricular fibrillation during any operation. By common usage the term has been expanded to include postoperative death and cardiac arrest from purely medical causes.

Incidence.—Reed and Hunt report an incidence of cardiac arrest in the operating room of 1:2,354 operations. It occurs most frequently in children, and the cardiac surgeon operating on damaged hearts will naturally encounter it most often.

Predisposing Factors

I Myocardial hypoxia

A Inadequate oxygenation

1 Preoperative

- a Cyanotic heart disease
- b Failing heart
- c Pulmonary disease and edema
- d Overoedation

2 During operation

- a Obstructed airway—poor pulmonary ventilation
- b Overdose of anesthetic
- c CO_2 retention

B Inadequate hemoglobin

1. Preoperative

- a Anemia, secondary or primary

2 During operation

- a Shock
- b Hemorrhage

C Inadequate coronary artery blood flow

1. Preoperative

- a Systemic hypotension—shock, hemorrhage

- b Coronary artery disease

Treatment

Stage I

2. During operation
 - a. Systemic hypotension
 - b. Hemorrhage
 - c. Drugs
 - d. Low cardiac output
 - e. Cardiac displacement
 - f. Coronary artery disease
- II Other Factors
 - A. Myocardial irritability occurring in coronary artery insufficiency and during administration of certain drugs, e.g., chloroform
 - B. Vasovagal reflex and hypoxia
 - C. Marked electrolyte imbalance and CO₂ retention

All factors mentioned may play a part in postoperative cardiac arrest.

A knowledge and the avoidance of these factors which may predispose to cardiac arrest may help to prevent a catastrophe in the operating room.

Proper oxygenation of the tissues under anesthesia is the responsibility of the anesthesiologist who, along with the surgeon, must be constantly on the alert and must give conscientious attention to details of drugs, airways, and ventilation (see Chapter 8).

Maintenance of Blood Pressure.—The heart rate and blood pressure reflect very rapidly the presence of many factors said to predispose to cardiac arrest. General tissue anoxia, due to such factors as poor ventilation and drugs, is at first reflected by a rise in blood pressure with comparatively slow pulse rate, followed rapidly by a blood pressure decline which may lead to cardiac arrest if not corrected. Generally a diminution of blood pressure below a systolic level of 80-90 mm Hg decreases coronary artery flow with resultant myocardial ischemia and irritability. It is advisable to keep blood pressure levels within 20-30 mm Hg of the average preoperative blood pressure level.

Recognition of Cardiac Arrest.—The two cardinal signs are the absence of a palpable pulse in major vessels and the disappearance of an audible blood pressure. *When these occur, open the chest.*

Don't waste time by listening for inaudible heart sounds or waiting for an ECG tracing. Don't inject drugs blindly into the heart or intravenously. Don't try to massage through the diaphragm. Don't worry about asepsis or skin preparation. Institute Stage I immediately. *You have only 3 minutes.*

Emergency Action

1. Adequate oxygenation of the blood
2. Restoration of circulating blood volume
3. Transport of oxygenated blood to vital centers.

Anesthetist

1. Notify the surgeon of cardiac arrest.
2. Note time.
3. Insert intratracheal tube and expand lung with oxygen. Use the breathing bag or mechanical respirator
4. Lower head of table
5. If blood loss has been excessive, start intravenous or intra-arterial transfusion
6. Check effectiveness of cardiac massage, blood pressure, and carotid pulse.

Surgeon

1. Check pulse in aorta or large vessels
2. If absent, make an anterior incision in 5th left intercostal space. Don't worry about bleeders.
3. Insert the right hand and squeeze the heart against the sternum. Release and compress rhythmically for several seconds
4. Pause to cut costal cartilages and insert rib spreader. Resume massage through the intact pericardium.
5. Pause to open pericardium longitudinally with each cardiac compression and fill between squeezes. Failure of heart to fill may be caused by (a) low blood volume (in which case, transfuse rapidly) and (b) Trendelenburg position insufficiently acute
6. Grasp heart between the palms of both hands and commence rhythmic compression from apex to base at 60-70 beats per minute

The emergency is over. With proper cardiac massage an adequate flow of blood can be maintained indefinitely.

Stage II

For Restoration of Heartbeat

1. Massage steadily and forcibly. Have anesthesiologist check pupils, blood pressure, and carotid pulse
2. Make certain that the ventricles are emptied with each cardiac compression and fill between squeezes. Failure of heart to fill may be caused by (a) low blood volume (in which case, transfuse rapidly) and (b) Trendelenburg position insufficiently acute

Increase angle to augment drainage of blood from feet and viscera.

3. Treat the flaccid heart muscle by injecting 3-5 ml. of 10% calcium gluconate into the left ventricle and by quickly massaging it through the coronary circulation.
4. Treat ventricular fibrillation, which can only be detected by opening the pericardium. This is one reason why cardiac massage performed through the abdomen may be ineffective in restoring heartbeat. Massage until the heart muscle is pink and the ventricles are well emptied; then apply the electric defibrillator electrodes.

2. Speed at which cardiac massage is started. After 3-3½ minutes irreversible cerebral changes occur. The return of a heartbeat with a normal blood pressure often occurs but the patient either dies in a few days or survives for many months or years as a decerebrate.

3. Effectiveness of massage. Unless the massage of the ventricles is sufficiently effective to provide a blood pressure of 60-80, the results will be poor.

In 1,200 cases collected by Stephenson, Reid, and Hinton a permanent survival rate of 28% was achieved. The prognosis was as good in

Fig. 235.—Diagram illustrating correct method of massaging the heart between the palms of the hands which enclose the two ventricles. The use of fingers and thumbs is ineffectual and leads to perforation of the ventricles. Drawing shows heart of patient postured in right lateral position and exposed through a left 5th interspace lateral thoracotomy, which is preferable. In emergency, an anterior left 5th interspace thoracotomy may be used.

Prognosis

This depends upon the following.

1. Cause of cardiac arrest. Functional cardiac arrest has a higher recovery rate than if the cause is organic

adults as in children. In the group that died, 87% did so within the first 27 hours, and only 3% after surviving for 6 days. In the entire group there were only eight so-called decerebrates who lived despite severe brain damage.

OPEN HEART SURGERY

The term *open heart surgery* is applied when operations are performed under direct vision, in a relatively bloodless field within the chambers of the heart or great vessels. To permit this type of operation, the venous inflow to the heart must be either completely obstructed or detoured about the heart by an extracorporeal heart-lung apparatus. Circulatory arrest by caval occlusion is tolerated for only a short time (about 3 minutes), but, by lowering body temperature the time limit can be extended sufficiently to permit certain intracardiac operations.

Hypothermia and Total Caval Obstruction

General body hypothermia reduces the metabolism of vital centers so that they can tolerate longer periods of circulatory arrest. The normothermic safety margin of 3 minutes is thus extended to 6-8 minutes at 30° C.

The advantage of hypothermia lies in its simplicity and in the small amount of special equipment necessary. The two main disadvantages are as follows: (1) the time limit of 6-8 minutes forces the surgeon to work under pressure and complex defects cannot be adequately repaired, and (2) the myocardial irritability and ventricular fibrillation become more frequent as the temperature drops. However, in the usual range of 28-30° C. ventricular fibrillation is much less frequent.

Hypothermia can be produced by external (surface) or internal cooling. Surface cooling is the usual technique and is accomplished by immersing the patient in an ice bath (Swan) or by refrigeration blankets (Bigelow). Internal hypothermia is less usual and is secured by cooling the blood (Brock), or by putting ice cubes in the thoracic cavity (Blades).

Indications.—The indications for the use of hypothermia to perform operations upon the open heart are still controversial. It is a satisfactory method for the repair of interatrial septal defects of the secundum type and for the opening of a pure stenotic pulmonary valve in infants and children. However, equally good results have been obtained by the use of the Gross well for atrial septal defects.

Hypothermia introduces a number of physiologic changes which may be harmful and which are at present not too well understood. Infants and children seem to tolerate the procedure better than adults. In some cases the working time allowed the surgeon is far too short to permit a satisfactory pro-

Fig. 236.—Diagram demonstrating extracorporeal circuit. The venous blood is removed from the venae cavae and pumped through an oxygenator, and the oxygenated blood is returned into the femoral artery (The aorta has been foreshortened for diagrammatic purposes).

cedure. However, in closed heart operations on poor-risk patients with either acquired or congenital heart disease, hypothermia may offer a considerable margin of safety because of the resultant lowered metabolic requirements.

Extracorporeal Heart-Lung Apparatus

The substitution of the human heart and lungs by a machine which perfuses the body with oxygenated blood to keep the patient alive while his diseased heart is repaired has long been the dream of those interested in heart surgery. The original apparatus was developed by Gibbon, who also performed the first operation on a human heart, using an apparatus of his own design.

There are several machines in use clinically today. They all have the same two basic components, i.e., (1) a pumping system to propel the blood to and from the apparatus, and (2) an oxygenator or artificial lung. It is with respect to the oxygenator, in particular, that the various machines differ. In the apparatus perfected by Lillehei and DeWall, the venous blood is oxygenated by bubbling oxygen through it. Other oxygenators expose, to a flow of oxygen, a large surface area on which a film of blood is produced. A third type of oxygenator in use today interposes a plastic membrane between blood and oxygen, a substitute alveolar membrane.

These machines have been used to repair a wide range of cardiac defects under direct vision. However, they are not entirely satisfactory and are still being modified.

SURGERY OF CONGENITAL MALFORMATIONS

CLASSIFICATION

There is still no better classification of congenital heart diseases than that of Abbott, which divides them into three classes.

Acyanotic Group.—This group includes patients in whom no abnormal communication exists between the two circulations but in whom the anomaly is liable to become the seat of strain, e.g., anomalies of the aortic arch and coarctation of the aorta.

Cyanose Tardive Group.—In this group patients have a predominant left-to-right shunt, which, however, may become reversed, producing cyanosis. This reversal occurs when the pressure on the pulmonary side of the defect exceeds that on the systemic side. In most patients with a patent ductus arteriosus, blood flows from systemic (high pressure) to pul-

monic (low pressure) circuits, so there is no cause for cyanosis. However, in the presence of heart failure or when the pulmonary artery pressure exceeds the systemic pressure, cyanosis can occur.

Cyanotic Group.—In cyanotic heart conditions, of which there are many types, the fundamental feature is the presence of venous blood in the aorta and its branches. This is due usually to some abnormal arrangement by which blood from the right ventricle gains access to the aorta (a right-to-left shunt).

Successful forms of treatment are available for patent ductus arteriosus, coarctation of the aorta, anomalies of the aortic arch, atrial septal defect, ventricular septal defect, tetralogy of Fallot, congenital aortic valve stenosis, sub-aortic stenosis, and pure pulmonary stenosis. Patients with total anomalous pulmonary venous return, tricuspid atresia, ostium atrio-ventriculare commune, and ostium primum interatrial defects are operable but the risk is greater. A satisfactory operation for transposition of the great vessels has yet to be devised, but the circulatory physiology of these patients can be improved by operation.

PATENT DUCTUS ARTERIOSUS

Embryology and Anatomy.—During fetal development the ductus arteriosus serves to conduct blood from the pulmonary artery to the aorta. This permits a large portion of blood issuing from the right ventricle to pass directly to the descending aorta, without traversing unarterialized lung tissue. Closure of the ductus arteriosus following birth normally occurs in two stages. Animal experiments indicate that the first stage or functional closure is generally complete within a few minutes after birth and is due to contraction of abundant muscular elements within its wall. This is followed by the second stage, a gradual fibrous obliteration of the ductus to form the ligamentum arteriosum. Investigation suggests that an adequate oxygen saturation of the systemic blood is necessary to initiate the first stage. The brief equalization of pressure between the systemic and pulmonary arterial systems following birth is considered by some to be important in allowing the muscular elements of this vessel to contract and obliterate

Fig 237

— "Congenital Cardiac Disease" exhibit at McGill University, Centenary Meeting of the British Medical Association, 1932, by Dr. Maude (Courtesy McGill University and The Montreal Children's Hospital)

the lumen. It has been suggested, therefore, that patency of the ductus arteriosus should not be considered as an anatomic error of development but rather as the result of an abnormal physiologic process. Christie's study of routine autopsies revealed that in 95% of specimens the ductus arteriosus was closed by the 12th week of life and in 99% by the end of the first year.

The ductus arteriosus is a funnel-shaped vessel originating from the aorta, just below the origin of the left subclavian artery, and joining the main pulmonary artery just to the left of its bifurcation. It is commonly approximately 1 cm in length but may be only represented by a fissure between the two vessels. Its diameter varies considerably.

Physiopathology.—Patency of this vessel after birth permits oxygenated blood to flow from the aorta to the pulmonary artery. The volume of blood shunted depends upon the size of the ductus and the pressure differential between the aorta and the pulmonary artery. Since the pressure within the aorta is normally higher than that within the pulmonary artery, the shunt of blood may be high and has been estimated as high as 80% of the left ventricular output. As the blood shunted has been oxygenated, its recirculation through the lungs serves no useful purpose but places a strain upon the left ventricle, which must pump considerably more blood than normal. Persistence of this shunt may result in an elevation of pulmonary artery pressure (pulmonary hypertension). The physiopathology then becomes more complex.

Diagnosis.—This should rarely present difficulty. Patients are usually of normal growth and stature, although underdevelopment may be observed. Frequently there are no complaints, and its presence becomes evident only during routine physical examination. Symptoms of palpitation, shortness of breath, and easy fatigability are sometimes elicited.

The characteristic physical finding is a murmur, best heard in the 2nd intercostal space, just to the left of the sternum. This is continuous throughout all phases of the cardiac cycle and has been termed "machinery-like." A palpable thrill is usually evident. An increased pulse pressure due to a low diastolic blood pressure is a common finding.

Although roentgenologic examination may reveal no abnormality, it is likely to demonstrate cardiac enlargement, a prominent main pulmonary artery, and increased pulmonary vascular markings, the latter being due to the increased flow of blood through the pulmonary vascular bed. The electrocardiogram may be normal but often reveals a left ventricular preponderance.

Complications.—The complications encountered are subacute bacterial endarteritis, aneurysm formation, cardiac failure, and pulmonary hypertension. Subacute bacterial endarteritis is most likely to affect the pulmonic end of the ductus and occurs most frequently after tooth extraction or secondary to other foci of infection. Degenerative disease may occur within the ductus wall with aneurysm formation. Left ventricular failure is encountered when the shunt of blood from aorta to pulmonary artery places too great a strain upon that organ. Pulmonary hypertension develops either as a result of a high flow of blood through the pulmonary vasculature or following pulmonary vascular changes (see section on pulmonary hypertension). Should pulmonary hypertension occur, right ventricular strain becomes evident.

Treatment.—The treatment is surgical obliteration, which can be accomplished by ligation in continuity or division of the ductus between clamps, and suture of the divided ends. The former technique is satisfactory for the majority of patients. If, however, the ductus is unusually wide and especially if it is thick-walled, division is advisable. The ductus is exposed through a left thoracotomy. The lung is deflected caudad, and a flap of mediastinal pleura raised off the aorta and lifted medially. The recurrent branch of the left vagus nerve, which courses below the ductus, serves as an identifying landmark and must not be traumatized. A pouch of pericardium overlying the lateral surface of the ductus is dissected off. The ductus is then ligated in continuity or divided between clamps and each of its ends oversewn. The operative mortality is less than 1%. Since the patient's cardiovascular physiology is normal following operation, resumption of full activities is permitted after one month.

Atypical Ductus Arteriosus

The majority of patients with a patent ductus arteriosus present typical clinical findings, and the diagnosis is not difficult. In some patients, however, the typical continuous murmur is not demonstrable, a systolic murmur alone being present. This occurs when the pressure within the pulmonary artery is sufficiently high that the diastolic pressure within it approximates the aortic diastolic pressure. Blood flows from aorta to pulmonary artery during systole with little or none during diastole.

Since the diagnosis of patent ductus arteriosus under such circumstances cannot be established by clinical examination alone, special investigation is necessary. At heart catheterization, the finding of an increased oxygen saturation within the pulmonary artery compared to the right ventricle is diagnostic.

The ductus arteriosus may also be visualized by aortography. With this technique, 35% Diodrast is injected rapidly toward the aorta by means of a catheter placed into the left carotid or brachial artery. In the presence of a ductus arteriosus the pulmonary artery is opacified simultaneously with the aorta. Catheterization, however, is used more often since the presence of complicating malformations and the associated altered hemodynamics can be better clarified by this means. It can be used successfully even in very small infants.

The circulatory physiology is seriously impaired. It is not surprising that patients in the infant age period are often seen and that they are usually retarded in growth and development. A history of repeated pulmonary infections is often given. A frequent finding is the presence of cardiac failure, which is often resistant to the usual medical management. Surgical intervention is usually lifesaving but may be contraindicated when pulmonary vascular changes secondary to pulmonary hypertension are of an advanced degree.

PULMONARY HYPERTENSION

In the newborn infant, the small pulmonary arteries normally are thick-walled muscular structures with a normal intima and a small

lumen, and the pulmonary artery pressure normally approaches that of the aorta. In the normal infant there is a gradual reduction in the thickness of the media of these vessels, and examination at 6 months reveals a thin-walled artery with a wide lumen. This is associated with a normal pulmonary artery pressure. It is well recognized that in a patient with a large left-to-right shunt, such as with a ductus arteriosus or a ventricular septal defect, the structures of the pulmonary arteries may change to resemble the infantile appearance with a thickened muscular coat. This pathologic state may progress to a stage of intimal fibrosis. The muscular hypertrophy is probably reversible with removal of the cause of the large pulmonary flow, while the intimal fibrosis is probably not.

Selection of patients for operation when pulmonary hypertension is present may be difficult. A patient with hypertension due to increased flow through the lungs will likely respond well to operation since pulmonary vascular changes are likely to be minimal or absent. This physiologic state is suggested by examination of chest by x-rays, which indicate evidence of increased pulmonary flow, i.e., increased vascular markings. Catheterization will confirm the presence of increased vascular flow through the lungs. Obliteration of left-to-right shunt will thus reduce the pulmonary flow, and the patient will be expected to respond well.

Conversely, obliteration of the ductus arteriosus may be contraindicated in the presence of advanced pulmonary vascular changes. An advanced degree of pulmonary arteriosclerosis increases the peripheral resistance of the vascular bed in the lungs to such a degree that pulmonary flow may be reduced below normal. Thus, x-rays of the chest are then likely to reveal that the pulmonary vascular markings are diminished. In this patient there may be clinical evidence of reversal of flow in the ductus (flow from pulmonary artery to aorta). The observation of cyanosis of the left upper extremity and lower extremities can only be explained by the escape of pulmonary venous blood from the pulmonary artery into the aorta and so into the left subclavian artery and descending aorta. A period of extreme

pulmonary hypertension in such a patient can thus be relieved through the patent ductus arteriosus. If, in this patient, the ductus is ligated, episodes of excessive pulmonary hypertension can no longer be relieved, and death results.

it is due to a progression of the obliterative process of the ligamentum arteriosum on to the aortic wall. The fact that in some cases the stenosis of the aorta is not at the point of attachment of the ligamentum arteriosum is evidence against this hypothesis. Coarctation

COARCTATION OF THE AORTA

Embryology and Anatomy.—Characteristically this anomaly consists of an eccentric constriction of the descending thoracic aorta just below the origin of the left subclavian artery. This is usually uncomplicated by other anomalies, but its combination with a bicuspid aortic valve, subaortic or aortic stenosis, or patent ductus arteriosus is possible. The etiology of this vascular defect is not understood. The suggestion has been given that

of the abdominal aorta and of the aortic arch has been described.

Types of coarctation of the aorta are classified by Johnson as follows:

- I Ductus arteriosus closed
 - a With collateral circulation
 - b Without or with inadequate collateral circulation (incompatible with life)
- II Ductus arteriosus open
 - 1 Proximal to coarctation
 - a With collateral circulation
 - b Without or with inadequate collateral circulation (incompatible with life)

2. Distal to coarctation

- a With collateral circulation
- (1) Pressure maintained by collateral circulation adequate to prevent flow from pulmonary artery to aorta
 - (2) Pressure maintained by collateral circulation inadequate to prevent flow from pulmonary artery to aorta
- b Without collateral circulation

circulation, stimulated by the presence of the coarctation, is largely through vessels issuing from the arch of the aorta and its branches to join intercostal arteries below the coarctation, where the blood flow is opposite to normal. It has been postulated that the hypertension cannot be entirely explained by the ob-

Fig 243—A, Diagram showing typical findings in patient with coarctation of the aorta. The major indentation occurs on the lateral wall of the aorta just distal to the origin of the left subclavian artery. The poststenotic dilatation of the aorta is shown, and the large, tortuous thin-walled intercostal arteries which join the aorta below the coarcted segment are visualized.
B, Technique of anastomosis after resection of the coarcted segment

I. Ductus Closed

Fig 241—Diagram of three types of coarctation of the aorta. Type I is commonest and is not associated with a patent ductus arteriosus

Physiopathology.—Type I coarctation of the aorta, the commonest variety encountered, results in elevated systolic and diastolic pressures proximally. Intra-arterial blood pressure recordings within the femoral artery have revealed that it is lower than normal and associated with a narrow pulse pressure. Collateral

II. Ductus Patent

struction in the aorta, but is partly due to the release of renin from the kidney.

Diagnosis.—The diagnosis of coarctation of the aorta is not difficult. The symptoms and signs depend upon the degree of constriction present and the presence or absence of complicating anomalies. Most patients with

coarctation fall into Type I and have no complaints, the diagnosis being made at routine examination. Males, who are the more frequently affected, are usually well developed and muscular. Complaints of headache, dyspnea on exertion, and palpitation may be given. Intermittent claudication is rarely noticed. The diagnosis can be made on physical examination, which reveals (1) hypertension in the upper extremities, (2) diminished or absent femoral artery pulsations and low blood pressure or imperceptible blood pressure by cuff

indentation of the aorta, best seen in the P.A. projection, is often demonstrable. Examination of the esophagus filled with barium reveals the so-called reversed 3 sign.

Complications.—Complications encountered include (1) cerebral hemorrhage due to rupture of a congenital aneurysm (present in approximately 20% of the patients) or rupture of an artery secondary to hypertension, (2) left ventricular failure, (3) aneurysm formation, or (4) subacute bacterial endocarditis. Statistics indicate that prior to the age

A, Notching of undersurfaces of ribs (not clearly seen after reproduction) and an indentation of descending thoracic aorta (arrow).

B, X-ray taken with the esophagus filled with barium demonstrates the reversed 3 sign (arrows) caused by impression of the esophagus by prestenotic aortic dilatation above and the poststenotic dilatation of the aorta below.

(Courtesy The Montreal Children's Hospital.)

in the lower extremities, (3) evidence of left ventricular strain, and (4) the presence of strongly pulsatile collateral vessels about the shoulder girdle. Chest x-rays may reveal notching of the undersurface of the first 7 ribs by enlarged, tortuous, intercostal arteries. This sign is not consistent, however, and is rarely seen prior to the age of 9 years. The actual

of 40 years, 75% of the patient will be in trouble from one of the above causes.

Treatment.—It is recognized that surgery is not indicated for every patient with coarctation of the aorta. Early operation is advised if the individual child or adult has symptoms referable to the malformations, such as marked hypertension, or if he has electrocardiographic

evidence of left ventricular strain. The optimum age for operation is 8-12 years. As with ductus arteriosus, a successful operation results in a normal circulation. Resection of the coarcted segment of aorta and end-to-end anastomosis is the preferred operation but, if this is not possible, as when a long segment of aorta is affected, the resected portion can be replaced by an arterial homograft or by a plastic prosthesis.

The results of operation are good. Operative mortality is low. The blood pressure falls gradually during the first 2-3 postoperative weeks. Resumption of full activity without restriction is permitted 6 weeks after operation.

Fig. 246.—A, Diagram of abnormality presented in pure pulmonary valvular stenosis. B, Technique of valvulotomy, using Brock procedure. C, Valvulotomy performed under direct vision, using hypothermia.

In patients who have a patent ductus arteriosus with coarctation of the aorta, operation may be indicated at an early age, due to the presence of a large left-to-right shunt through the ductus arteriosus. The decision to resect the coarctation of the aorta at the same time should be made only if collateral circulation is sufficient to permit clamping the aorta for the time necessary to resect and anastomose

PURE PULMONARY STENOSIS

Anatomy.—Congenital stenosis of the pulmonary valve without other complicating abnormalities is the commonest form of this anomaly. The valve cusps are fused, and there is a small central orifice which permits blood to escape from the right ventricle to the pulmonary artery. A poststenotic dilatation of the main pulmonary artery is almost invariably present.

Stenosis of the outflow tract of the right ventricle, i.e., an infundibular stenosis, may be encountered, and a combined valvular and infundibular stenosis is possible. A patent foramen ovale is not uncommon. A patent

ventricular septal defect in association with an infundibular stenosis has been described.

Physiopathology.—Pulmonary blood flow is diminished due to the obstructing abnormality between the right ventricle and pulmonary artery. Hypertrophy and dilatation of the right ventricle due to an elevated right ventricular pressure is found. A right-to-left shunt with cyanosis is possible in the presence of

Fig 247—X ray of chest in patient with pure pulmonary valvular stenosis revealing a prominent main pulmonary artery (arrow) due to poststenotic dilatation and diminished vascular markings in the lung fields (Courtesy The Montreal Children's Hospital)

a patent foramen ovale or other septal defect when the right atrial pressure exceeds the left.

Diagnosis.—Most patients are acyanotic but, in the presence of an atrial septal defect with a right-to-left shunt, cyanosis may be present. Dyspnea during exercise is the principal complaint.

On physical examination the second pulmonic sound is characteristically diminished or absent, and there is a grade 4, harsh systolic murmur, best heard in the pulmonic area. X-rays of the chest reveal that the pulmonary vascular markings are diminished, the outline of the main pulmonary artery is prominent, and the heart is enlarged due to hypertrophy and dilatation of the right ventricle. The electrocardiogram demonstrates right ventricular hypertrophy.

Valuable information is obtained by cardiac catheterization. The presence of a high right ventricular pressure and a low pulmonary artery pressure without evidence of left-to-right shunt confirms the diagnosis. By obtaining a pressure tracing during withdrawal of the catheter from the pulmonary artery to the right ventricle, it is possible to clarify the nature of the obstructing lesion. A pure

valvular stenosis is indicated by a low pressure in the pulmonary artery and the abrupt appearance of an elevated pressure when the catheter reaches the right ventricle.

In the presence of a valvular and an infundibular lesion, the transition from low to high pressure will be more gradual as the catheter is pulled back from the pulmonary artery into the chamber between the pulmonary valve and infundibular bar and then into the right ventricle.

Treatment.—Selection of patients for operation is based on the presence or absence of symptoms and on the evaluation of the physiopathology as clarified by laboratory investigation.

Pulmonary valvulotomy is performed for pulmonary valvular stenosis, whereas excision of the stenotic area is required to cure infundibular stenosis.

Pulmonary valvulotomy may be accomplished blindly through a small incision in the right ventricular wall, through which a valvulotome is introduced into the right ventricle. The cutting blades of the valvulotome are then opened and the instrument forced through the valve into the pulmonary artery. By this means a bicuspid pulmonary valve is created. This operation is associated with a low operative mortality and patients are symptomatically greatly improved. Although post-operative catheter studies often reveal a satisfactory drop of right ventricular pressure, this is not always consistent.

Fig 248—Blood pressure tracing recorded during heart catheterization and while the tip of the catheter is withdrawn from the pulmonary artery into the right ventricle. A low pulmonary artery pressure with an abrupt rise as the tip of the catheter slips past the pulmonary valve demonstrates the presence of a pure pulmonary valve stenosis. (Courtesy The Montreal Children's Hospital)

Pulmonary valvulotomy, however, is best performed under direct vision, which permits a more extensive operation upon the valve and a greater assurance of a complete valvulotomy. This is accomplished with the patient under hypothermia and with arrest of circulation achieved by temporary occlusion of both venae cavae. The pulmonary artery is then incised and the valve cut under direct vision. Postoperative catheter studies have indicated that this results in a more consistent reduction of the right ventricular pressure. Similar direct valvulotomy can be performed while the heart is excluded from the general circulation, using an artificial heart-lung apparatus.

ANOMALIES OF THE AORTIC ARCH AND ITS PRIMARY BRANCHES

Abnormalities of these vessels can produce complications due to compression or distortion of the esophagus and trachea.

Right Aortic Arch

A right aortic arch is not an uncommon finding in association with other severe cardiac malformations. It may appear, however, as a single entity. The arch is directed to the right of the esophagus and trachea and may descend on the right or traverse behind the esophagus and trachea to descend to the left of the midline. This course alone, although it may

Fig. 249—X-ray of the chest (with explanatory diagram) in a patient with a "vascular ring" caused by the esophagus filled with barium, demonstrating a posterior indentation of the esophagus caused by the aorta as it traverses the mediastinum from right to left. There is also compression of the trachea (Courtesy The Montreal Children's Hospital)

The results of operation using hypothermia, with inflow caval occlusion and division of the valve under direct vision, are good. The mortality rate is low and the circulatory hemodynamics returns to normal in most patients.

distort the esophagus, is not likely to produce symptoms, since the capacity of the mediastinum is such that obstruction of the esophagus and trachea does not occur. The presence of a ductus arteriosus or ligamentum arteriosum connecting the main pulmonary

artery to the descending aorta completes a ring of vessels about the trachea and esophagus. The ring thus formed is made up of the ascending aorta in the midline, the arch of the aorta to the right, the terminal portion of the arch and first portion of the descending aorta behind the trachea and esophagus, and the ligamentum arteriosum or patent ductus arteriosus to the left. It is possible for this configuration of vessels to compress the trachea and esophagus sufficiently to cause complaints.

Diagnosis.—The principal complaint may be dysphagia due to distortion of the esophagus. The history of repeated episodes of bronchopneumonia, particularly when associated with a persistent brassy cough, is suggestive of the presence of the malformation and is secondary to narrowing of the trachea by the vascular ring.

Examination of plain films of the chest may reveal compression of the trachea. Confirmation of the presence of a tracheal or esophageal compression is obtained by barium swallow.

An oblique indentation of the posterior aspect of the esophagus, caused by the arch traversing from right to left, and an indentation of the side of the esophagus, caused by a persistent ligamentum arteriosum, are demonstrated during fluoroscopic examination of the barium-filled esophagus. The combination of tracheogram and esophagogram to ascertain the precise nature of the ring is rarely indicated.

Treatment.—Operation may be indicated at an early age in order to obviate complications resulting from this abnormality. At operation a wide dissection of the mediastinum is performed to clarify the type of vascular anomaly. A ligamentum arteriosum, which completes the ring, is divided. Further dissection and displacement of vascular structures relieve any persistent compression of the trachea and esophagus.

Double Aortic Arch

In this malformation the ascending aorta splits into two main trunks which encircle the esophagus and trachea, joining to form the descending aorta. This abnormality is due to the persistence of both right and left

branchial arteries. In most instances the anterior or left arch is smaller than the posterior one.

Although this anomalous arrangement of vessels may produce no complaints and no complications, compression of the esophagus and trachea is possible. The complaints are similar to those previously described and the diagnosis is suggested by the type of investigation given above. Surgical therapy is undertaken in the presence of dysphagia or respiratory complications. At operation the smaller limb, usually the anterior, is selected for division, which is made in such a manner that circulation to the head and neck is not compromised. As with the surgical treatment of anomalies associated with the right aortic arch, the vessels are displaced and sutured in such a manner that further compression will not occur.

Anomalous Origin of Cephalic Arteries

Bayford (1789) described a malformation consisting of anomalous origin of the right subclavian artery, which arose from the left side of the aortic arch and, as a result of its course to reach the right upper extremity, traversed behind the esophagus, compressing it forward in so doing. This caused severe dysphagia, and so the descriptive term *dysphagia lusoria* was given by this author. It is recognized that such compression may be caused by an abnormal course of other cephalic vessels which may indeed traverse between esophagus and trachea rather than behind them.

The presence of this abnormality is suggested by fluoroscopic examination of the barium-filled esophagus. Operation is indicated in the presence of dysphagia. The subclavian artery or other vessels are exposed and divided between ligatures, and all strands of tissue which may cause a persistence of esophageal distortion are similarly freed.

ATRIAL SEPTAL DEFECT

Differentiation should be made between the two types of atrial septal defect, i.e., *ostium secundum* and *ostium primum*. In *ostium secundum*, due to inadequate development of the secondary septum, a large defect remains (commonly including the foramen ovale).

Such defects are situated in the upper and posterior parts of the interatrial septum and have normal septal tissue between the defect and the atrioventricular canal. *Ostium primum* defects, on the other hand, are rare and are situated in the lower part of the interatrial septum. They are due to persistence of the ostium primum because the septum primum failed to descend and unite with the cushion between the atrioventricular orifices. Their close association with the mitral and tricuspid valves accounts for the fact that the latter are commonly deformed.

Fig 250.—Diagram demonstrating a secundum type of interatrial septal defect. The venous return to the heart has been diverted to a pump oxygenator. Suture closure of the defect is being accomplished by an approach through the right atrium.

Diagnosis.—In most patients blood flows across the defect from the left atrium to the right atrium; consequently there is absence of cyanosis. In early life there may be no related complaints or disability, but many patients will exhibit a gracile habitus and shortness of breath on exertion. On physical examination a precordial thrill may be palpated and a grade 3 systolic murmur heard at the

left 2nd intercostal space just to the left of the sternal border. These findings are suggestive of the diagnosis of an atrial septal defect. The electrocardiogram in a high proportion of patients exhibits a so-called partial right bundle branch block, which is important evidence in favor of this diagnosis. Fluoroscopic evidence in favor of this diagnosis of oscopy reveals considerable enlargement of the right atrium and ventricle and markedly increased pulmonary vascular markings. The aorta is not prominent. Confirmation of the diagnosis is obtained by heart catheterization.

It is important to differentiate this defect from the anomalies of the pulmonary veins which, instead of draining into the left atrium, enter the right atrium or venae cavae. This may be possible by the use of angiocardiology and by the study of dye dilution curves.

Treatment.—Successful closure of atrial septal defects of the secundum type has been accomplished by several different techniques. First attempts at obliteration of the defect were made by invaginating portions of the atrial wall into the defect and suturing them in place. Swan experimentally used the tip of the atrial appendage inverted into the defect. Subsequently, Bailey modified this technique by inverting the lateral wall of the atrium to the rim of the defect, using as a guide the finger introduced into the atrium via the right atrial appendage. Modifications of this technique have included the use of pericardium and plastic materials attached to the atrial wall. Subsequently, Gross described the use of a rubber well sutured to the side of the atrium. This permitted the surgeon to introduce sutures to repair the defect by placing instruments into the atrium via a well containing blood. More recently it has been shown by Sondergaard that it is possible to dissect the plane between the right atrium and the right pulmonary veins in such a manner that a circular suture can be passed through the lower portion of the atrial septum which, when tightened, closes the atrial septum. It should be emphasized that all these techniques are blind or closed heart methods, the manipulation being carried out by touch. Other methods have permitted suturing the defects under direct vision with the interior of the right atrium widely exposed. This has

been successfully accomplished during hypothermia with the venous return to the heart obstructed temporarily. It has also been possible during temporary by-pass of the heart and lungs, using an artificial heart-lung machine. The chamber is explored through an incision placed in the atrium. The defect or defects are then closed by means of a running suture or by stitching a plaque of Ivalon sponge to the edges of the defect.

It cannot be overemphasized that selection of patients for operation is important. The operative mortality of patients with a primum type of defect is high. The results of operation with the secundum type, however, are eminently good. As with patients having a patent ductus arteriosus, evaluation of the pulmonary hypertension is important since, if it is of systemic levels with established pulmonary vascular changes, closure of an atrial septal defect is usually contraindicated.

VENTRICULAR SEPTAL DEFECTS

Anatomy.—In this malformation there is a defect in the septum between the right and left ventricles. The various anomalies have been classified according to whether they occur in the inflow or outflow tracts of the right ventricle. The outflow portion of the right ventricle may be defined as that part lying between the pulmonary valve above and the nearest portion of the tricuspid valve below. Those related to the outflow tract seem more common, and defects just inferior to the crista supraventricularis are most often encountered. Multiple defects have been described.

Physiopathology.—The presence of a ventricular septal defect permits a shunt of blood from left to right ventricle. Should the defect be small, the volume of blood shunted may not cause significant alteration of the circulatory dynamics. However, a large shunt of blood results in a greatly increased pulmonary vascular flow. There is a strain upon the left ventricle since it must pump a greatly increased volume of blood. The presence of this large left-to-right shunt is likely to result in pulmonary hypertension which, as with the patent ductus arteriosus, may place a strain on the right heart and may become irreversible.

Diagnosis.—The patient with this lesion is acyanotic since the shunt of blood is from left to right. Growth and development may be normal, but in the presence of a shunt of an appreciable level the child may appear thin and frail, and his growth is likely to be retarded.

Characteristically, on physical examination the heart is enlarged, and a loud systolic thrill and murmur are present. The latter is of a harsh, rasping quality of maximal intensity in the 3rd and 4th intercostal spaces. X-rays of the chest reveal cardiac enlargement, a prominent main pulmonary artery, and increased pulmonary vascular markings. Cardiac

Fig 251.—A ventricular septal defect caudad to the crista supraventricularis. Exposure is obtained during by-pass of the heart by means of heart-lung machine. A patch of Ivalon has been prepared for suturing to the edges of the defect.

catheterization is employed in order to confirm the diagnosis and to provide information regarding the abnormal physiologic state.

Treatment.—Closure of the ventricular septal defect has been made possible with the development of artificial heart-lung machines. Such apparatus permits exposure of the defect and its closure under direct vision. The heart is widely exposed through a bilateral thoracotomy incision. With the patient's blood

diverted by means of the artificial heart-lung apparatus, an incision is made in the wall of the right ventricle. The nature and site of the defect are determined, and closure is accomplished by direct suture or by application of an Ivalon pledget to fill the defect. The risk from operation seems related to the size of the lesion and to the degree of associated physiopathology. Operation on patients with pulmonary hypertension of a high degree may be technically successful, but the incidence of complete heart block following operation is higher than in those with a lesser degree of pulmonary hypertension

stenosis of the pulmonary valve or the orifice of the pulmonary conus, high interventricular septal defect, and hypertrophy of the right ventricle.

Physiopathology.—From a knowledge of the anatomic arrangement it is understood that blood entering the right atrium flows to the right ventricle, where it cannot readily go to the pulmonary artery because of the pulmonary stenosis and, since the aorta arises from both right and left ventricles, venous blood escapes directly into the aorta along with blood from the left ventricle. As a consequence the pulmonary flow is reduced.

Fig. 252.—Diagram demonstrating types of deformity in tetralogy of Fallot. The outflow tract of the right ventricle is narrowed (infundibular stenosis). The aorta is overriding, and an interventricular septal defect is present.

A, Technique of Blalock operation.

B, Technique of Potts operation.

The operative mortality rate of patients under 2 years of age is high. A successful operation is curative, and a normal cardiovascular system is the result.

TETRALOGY OF FALLOT

Anatomy.—The tetrad of Fallot consists of dextroposition (overriding) of the aorta,

The systemic blood with its admixture of venous blood from the right ventricle accounts for the degree of cyanosis present. The hematopoietic tissue responds in an attempt to compensate and an excessive number of red blood cells are produced so that blood samples show a high red blood count, hemoglobin, and hematocrit reading.

Diagnosis.—In patients with this anomaly, cyanosis is generally observed from birth or within a few months. Retardation of growth, shortness of breath, and easy fatigability are common findings. When tired, such patients characteristically tend to squat rather than to sit or lie down.

Fig 253—X-ray of a patient with tetralogy of Fallot. The typical boot shape of the cardiac contour is revealed. The outline produced by the main pulmonary artery (arrows) is concave, and the pulmonary vascular markings are reduced. (Courtesy The Montreal Children's Hospital.)

On physical examination, in addition to cyanosis, clubbing of the fingers and toes is present. A thrill may be palpable over the precordium. Auscultation reveals the presence of a harsh systolic murmur heard over the base of the heart. Laboratory examination demonstrates polycythemia and an elevated blood hemoglobin. Characteristically, roentgenologic examination demonstrates that the heart is of normal diameter but boot-shaped in contour. The outline of the pulmonary artery is generally concave. Pulmonary vascular markings are, as one might expect, diminished. Right ventricular hypertrophy is the typical electrocardiographic finding.

A correct diagnosis can frequently be made after clinical examination alone, but in some instances special procedures must be undertaken. Angiocardiography will demonstrate that dye injected into a systemic vein will be seen to fill the aorta and pulmonary artery

simultaneously. This suggests that the aorta overrides the right ventricle.

At heart catheterization, pressure recordings reveal a normal or low intrapulmonary artery pressure and a high right ventricular pressure indicative of an obstruction between the right ventricle and pulmonary artery. In addition, the pulmonary artery blood flow is diminished, and the systemic arterial blood is unsaturated. Table 19 gives the report of a 5-year-old child, height 44½", weight 50 lb., body surface area 0.83 M².

Complications.—(1) Cerebral accident secondary to thrombosis within a cerebral artery and (2) anoxic spells which, in some patients with severe degrees of this malformation, result in episodes of unconsciousness.

Fig 254—Venous angiocardiogram in transposition of great vessels. This demonstrates the opaque medium filling the superior vena cava, right atrium, and right ventricle and passing from the right ventricle into the transposed aortic root, then outlining the aortic arch. (Courtesy The Montreal Children's Hospital.)

Treatment.—Two fundamentally different forms of treatment are available. In the first, a partial recirculation of systemic mixed venous and arterial blood from the aorta, through the lungs, results in an elevation of the systemic blood-oxygen saturation. This form of therapy does not alter the structural abnormality. The second approach is aimed at surgical correction of the malformation.

Treatment by Systemic Pulmonary Artery Anastomosis.—The purpose of this type of operation is to create an anastomosis between

CARDIAC SURGERY

Mid right ventricle	12.90	68.0		60	90
High right ventricle (subvalvular)	13.78	72.7	16.0	7.0	90
Left pulmonary artery	13.04	68.7	15.0	52.0	610
*Main pulmonary artery	13.10	69.0	88.0		
*Femoral artery	15.76	82.1			
*Oxygen consumption	= 126 ml/min				
Oxygen capacity	= 18.98 ml/100 ml blood				

$$\text{Systemic flow} = \frac{126 \times 100}{15.76 - 12.29} = 4,632 \text{ ml/min} = 5,378 \text{ ml/M}^2/\text{min}$$

$$\text{Effective pulmonary flow} = \frac{126 \times 100}{12.6 - 13.04} = 2,018 \text{ ml/min} = 2,430 \text{ ml/M}^2/\text{min}$$

$$\text{Total pulmonary flow} = \frac{126 \times 100}{18.54 - 13.04} = 2,290 \text{ ml/min} = 2,759 \text{ ml/M}^2/\text{min}$$

$$\text{Right-to-left shunt} = \frac{18.54 - 13.04}{4,632 - 2,018} = 2,614 \text{ ml/min}$$

$$\text{Left-to-right shunt} = \frac{2,290 - 2,018}{2,018} = 272 \text{ ml/min}$$

Comment: Pressures in the pulmonary artery were normal. Significant stenosis was demonstrated, both at the pulmonic valve and about 1 cm below the valve in the right ventricular outflow tract. Systolic pressures in the right ventricle and the femoral artery were almost identical. Bi-directional shunting was demonstrated at the high ventricular level, the right-to-left predominating.

Conclusions: Tetralogy of Fallot with pulmonic valvular and infundibular stenosis and predominant right to-left shunt.

*Simultaneous observations

the aorta or one of its branches and a pulmonary artery. This permits a portion of the mixed venous and arterial blood within the aorta to flow to the lungs. This shunted blood returns to the left atrium fully oxygenated. The effect of this alteration in blood flow is that the average level of oxygenated blood in the systemic system is increased, resulting in a diminution or complete disappearance of cyanosis, a reduction of polycythemia and consequent danger of cerebral thrombosis, and, of greater importance, an increase in the exercise tolerance of the patient.

The operation may be accomplished by joining the end of a systemic artery (preferably a subclavian artery) to the side of the ipsilateral pulmonary artery—the Blalock operation. A similar result may be achieved by anastomosis of the side of the descending thoracic aorta to the side of the ipsilateral pulmonary artery—the Potts operation.

Corrective Operations.—The Brock operation, described by Sir Russell Brock, consists of the removal of the obstruction to pulmonary blood flow, whether due to pulmonary valve or infundibular stenosis. Pulmonary valvulotomy is performed by inserting a valvulotome into the right ventricle through a small incision. This instrument is then directed through the pulmonary valve which it splits during its passage into the infundibulum (infundibulotomy) is performed by biting out segments of the obstructing muscular structure within the right ventricle. The use of an artificial heart-lung apparatus has made a more complete corrective operation possible. With the heart-lung apparatus and the heart widely exposed, a long right ventricular incision is made. Under direct vision, pulmonary valvulotomy or infundibulotomy is accomplished, and the interventricular septal defect and over-

riding of the aorta are treated. If the outflow tract of the right ventricle is then not sufficiently wide, it can be increased by sewing a piece of Ivalon sponge between the cut edges of the right ventricle.

The results of this type of operation have become impressively good. Although the operative mortality is currently higher than that incurred with the Blalock or Potts operation, the indications are that the long-term results may be better.

OTHER CYANOTIC MALFORMATIONS WITH DIMINISHED PULMONARY FLOW

This category includes patients with tricuspid atresia, pseudotruncus arteriosus, and a common ventricle with pulmonary stenosis. The essential features are an obstruction of the flow of blood between the right atrium and the lungs and a septal defect, either atrial or ventricular or both, which permits venous blood to escape into the aorta.

In carefully selected patients, a systemic to pulmonary artery anastomosis is beneficial. The risk of operation in all is considerably higher than with tetralogy of Fallot, and the results in general are not as good. The exception to this is the trilogy of Fallot, pulmonary valve stenosis with an atrial septal defect which can be treated by valvotomy and closure of the septal defect. This operation is curative and may be performed during inflow occlusion under hypothermia or with a heart-lung machine.

TRANSPOSITION OF THE GREAT VESSELS

In this condition, the pulmonary artery originates from the left ventricle and the aorta from the right ventricle. An associated ventricular septal defect, patent foramen ovale, or patent ductus arteriosus is commonly observed. Other coexisting malformations, such as a right aortic arch, pulmonary valvular stenosis, coarctation of the aorta, and a stenosis of other valves, have been observed. The principal defect, the transposition of the aorta and the pulmonary artery, may be complicated by a variety of other anomalies of the heart and great vessels. The principal malformation has been ascribed to the failure of the aortic-pulmonary septum to spiral.

Physiopathology.—Although the abnormality permits survival of the fetus without compromising the function of the heart or oxygenation of the tissues, the situation is greatly altered following birth. In the newborn infant, with transposition of the great vessels, blood which enters the right atrium and right ventricle is expressed to the aorta, whereas pulmonary venous blood returning to the left ventricle is pumped out to the pulmonary artery. It is clear that survival would not be possible unless mixing of venous and arterial blood were possible. The presence of an atrial or ventricular septal defect may permit sufficient mixing of venous and arterial blood for the infant to survive. However, in most patients the strain placed on each ventricle is great, and they become dilated and hypertrophied in early life. The patients often die of cardiac failure within the first year of life.

The presence of venous blood in the systemic circulation accounts for the degree of cyanosis. If a septal defect is absent, cyanosis will be intense and survival beyond a few days or weeks will not be expected. In the presence of a large septal defect with sufficient mixing of blood, cyanosis may not be as obvious and indeed may be present only when the child cries lustily. It is characteristic, however, that cyanosis progressively becomes more intense.

Diagnosis.—Cyanosis is usually obvious from birth and may be very intense. The infant characteristically fails to thrive and exhibits marked dyspnea. Auscultatory findings are not characteristic and vary according to the type of secondary malformation present. X-ray and fluoroscopic examination is usually significant since it reveals a marked enlargement of both ventricles. This enlargement is rapidly progressive, as revealed when x-rays taken soon after birth are compared with ones taken 2-3 months later. There is evidence of pulmonary vascular congestion, and with fluoroscopy careful evaluation can often indicate the abnormal origin of the great vessels. Electrocardiograms commonly indicate a combined ventricular enlargement. Diagnosis may be confirmed by means of heart catheterization or by the use of angiocardiography.

Complications.—Death may result from cardiac failure or during an anoxic spell.

Treatment.—This malformation has been a perplexing one in regard to the development of an operation which could be expected to improve the patient. Attempts have been made to increase mixing of venous and arterial blood by the creation of an atrial septal defect and by a systemic to pulmonary artery anastomosis. Others have tried to transpose the aorta to the left ventricle and the pulmonary artery to the right. These procedures have met with little success.

It has recently been recorded that the circulation can be improved by partially transposing the venous return to the heart. In the Baffes operation, the principal procedure consists of transplanting the right pulmonary veins to the right atrium and directing the inferior vena cava blood to the left atrium. By this means the right pulmonary venous blood returns to the right atrium and is then delivered into the right ventricle and so to the aorta. The inferior vena cava blood is redirected to the left atrium, the left ventricle, and consequently to the pulmonary artery. The operative procedure is accomplished as follows: The right pulmonary vein is divided and its distal end sutured to the side of the right atrium. The inferior vena cava is connected with the stump of the divided right pulmonary vein by means of an aortic graft. Subsequent to this the junction between the vena cava and the right atrium is ligated. This ensures that all of the blood returning to the heart via the inferior vena cava is directed through the graft and through the stump of the right pulmonary vein to the left atrium.

The operative mortality for this operation is high, being in the vicinity of 50%. There has been a sufficiently high increase in exercise tolerance and improvement in general condition of the patients who have survived that the operation should be seriously considered for a patient with transposition of the great vessels. It is impressive indeed to observe a small infant with this sort of serious heart ailment undergo a major technical operation and be so obviously improved following the operation.

ACQUIRED HEART DISEASE

TRAUMA

The earliest form of heart surgery was concerned with the treatment of wounds. Although these were almost invariably fatal, they formed the basis for the development of cardiac surgery.

Since all forms of heart trauma may be complicated by hemopericardium, the recognition of acute cardiac compression is essential.

Cardiac Compression

Cardiac compression (tamponade) interferes with cardiac action by preventing adequate ventricular filling. In the acute form, death occurs if the tamponade is not relieved. The heart will tolerate a considerable degree of chronic compression, but inevitably cardiac failure ensues.

Acute compression, whether due to exudate from pericarditis or from bleeding into the pericardium, presents the characteristic signs of the *Beck triad*: (1) a small quiet heart, (2) rising venous pressure, (3) falling arterial pressure. Unless the pressure is relieved, the patient will die. The treatment of choice is pericardial aspiration. Operation is rarely necessary.

Trauma to the Heart and Great Vessels

Traumatic lesions may be divided into (1) contusions, (2) penetrating wounds, and (3) foreign bodies within the heart or its chambers.

Contusions.—Nonpenetrating trauma to the chest or abdomen may result in cardiac contusion. The steering-wheel injury is a frequent example. The diagnosis rests, to a large extent, upon the surgeon's awareness of the possibility of such injuries which vary greatly in their symptomatology and complications.

The patient may be asymptomatic, or he may develop angina, myocarditis with or without failure, coronary thrombosis with or without infarction, delayed rupture, or thromboembolism. Frequently arrhythmias or conduction disturbances are manifested. Such cases are best treated medically, including pericardiocentesis where there is evidence of hemopericardium and tamponade. Surgery has proved effective in the treatment of structural

Fig 256—Technique of closing laceration of ventricle

defects such as rupture of the cardiac septa or the aortic valve. The aorta may be ruptured and a false aortic aneurysm develops.

Penetrating Wounds.—Penetrating wounds, most often caused by bullets or stabbing, result in massive hemorrhage or acute compression. The entrance wound need not even be in the thorax, and tamponade may mimic hemorrhagic shock.

Ravitch and Blalock have advocated conservative treatment for cardiac wounds and point out that if cardiac compression is re-

lieved by pericardial aspiration, the bleeding usually ceases spontaneously. If bleeding continues, thoracotomy and repair of the wound are indicated.

Foreign Bodies.—Foreign bodies in the heart, rarely seen in civilian life, give rise to complications in 50% of cases. These may be emboli, cardiac aneurysm, myocardial rupture, abscess, ulcerative endocarditis, or psychologic disturbance from worry. Foreign bodies should be removed only if definitely indicated.

PERICARDITIS

Anatomy.—The pericardium is composed of two layers: (1) the *parietal pericardium* which consists of an outer *fibrous layer* lined by a *serous membrane*; (2) the *visceral pericardium* which is the reflection of the inner serous layer of the parietal pericardium over the base of the great vessels and over the heart (*epicardium*). The serous layer thus forms a continuous membrane which is the *pericardial sac*.

Classification of Pericarditis

Acute	Chronic
Serofibrinous	Chronic (pericarditis)
Hemorrhagic	Adhesive (pericarditis)
Purulent	Constrictive (pericarditis)
	Adhesive mediastinopericarditis

Acute Pericarditis

The rapid accumulation of fluid in the pericardium produces the signs of cardiac compression. The *Beck triad* plus tachycardia and orthopnea are present. When the fluid is nonpurulent there may be an intermittent low-grade fever, when there is pericardial pus, the constitutional signs of infection are present.

X-ray examination may show a typical pattern and is useful in the detection of pockets of pus. The ECG may show the typical pattern.

Differential Diagnosis.—Occasionally acute pericarditis that has progressed to the stage of cardiac failure is difficult to differentiate from *cor bovinum* which also presents a markedly widened heart shadow.

Treatment.—Pericardiocentesis is usually performed under local anesthesia with the patient sitting. A needle is inserted between the xiphoid and left costal margin and directed upward through the diaphragm into the pericardium. The removal of serous fluid is therapeutic. If pus is withdrawn, pericardial drainage (pericardiostomy) can be done under

Fig 257.—Diagram demonstrating a method of pericardiocentesis (From Vinberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max: *Surgical Errors and Safeguards*, ed 6, Philadelphia, J. B. Lippincott Co.)

local anesthesia. One of two approaches may be used. (1) resection of the 7th left costal cartilage or (2) below the left costal margin, by reflecting the attachment of the abdominal muscles.

Chronic Pericarditis *Constrictive Pericarditis*

Etiology.—Tuberculous pericarditis is the commonest cause. Suppurative and serofibrinous pericarditis account for a small percentage of cases, and recently it has been reported that organizing hemopericardium may result in constriction. Postoperative drainage of the pericardium is thus extremely important.

Pathology.—During acute pericarditis, fibrin is deposited on the serous surfaces of the pericardial sac. Organization results in contracting scar tissue which may become calcified.

Hemodynamics.—Because the cardiac chambers are constricted, ventricular filling is decreased. Venous congestion and its sequelae occur. This picture is similar to that of congestive failure, although the myocardium is intact. However, changes in the aortic-coronary pressure gradient and low cardiac output may produce true myocardial failure as well. These latter cases have a poorer prognosis following surgery.

Clinical Picture.—The patient rarely gives a history of tuberculosis. Fatigability, abdominal enlargement, dependent edema, and dyspnea are the usual symptoms. Mild peripheral cyanosis and venous engorgement, hepatomegaly, ascites, and hydrothorax are usually present. Blood pressure is low with a relatively high diastolic pressure, and venous pressure is markedly elevated. X-ray may show a normal heart size. Absent pulsation of the cardiac chambers, on fluoroscopy, and the

Fig. 258—Infrared photograph demonstrating the venous distention of the upper extremities, neck, and thorax to the level of the 2nd interspace, caused by pericardial occlusion of the superior vena cava due to constrictive pericarditis (Courtesy Montreal Heart Institute)

presence of calcification are important signs. Calcification is the only pathognomic sign of pericarditis, but constriction is not necessarily present. The Beck triad again is evident.

Treatment.—The aim is to remove the constricting scar which prevents the heart from filling. This is termed *cardiac decortication* or *pericardiectomy*. The approach to the pericardium can be made either through a median sternotomy, as recommended by Holman and Willett, or by a transsternal incision opening both pleurae, as favored by Johnson and Kirby. Other incisions made adequate decortication difficult. There are usually two distinct layers of scar tissue, of which the inner layer is tightly adherent to the heart and must be removed by sharp dissection. The principle of first freeing the outflow tract is followed

First the left ventricle, then the right side and finally the venae cavae are decorticated. Care must be taken to avoid injury to the coronary vessels and perforation of the heart. At the conclusion of operation the superior vena cava pressure should be less than 10 cm. of water. Antituberculosis therapy is given postoperatively.

Results.—Holman and Willett report 265 cases with 22 operative and 48 postoperative deaths. Of the 265, 118 patients were cured and 44 improved. Bigelow reports 13 cases with 2 deaths, and the cure of all survivors.

VALVULAR DISEASE

Etiology.—Rheumatic fever is by far the commonest cause of acquired valvular disease. Frequently, however, no history of rheumatic

A

fever can be obtained and sometimes the only past illness is scarlet fever or tonsillitis.

The effects upon the heart valves may be divided into three main groups.

1. *Valvular stenosis.* The valve is narrowed, impeding the forward flow of blood.
2. *Valvular insufficiency.* The valve permits a retrograde flow of blood after it is closed.
3. *Combined valvular stenosis and insufficiency.*

Clawson et al. found at autopsy that the valves are involved in the following frequency: mitral 73%, aortic 62% tricuspid 10%, and pulmonic 3%. The mitral valve alone was

leaflet. At their periphery the leaflets are attached to the annulus which surrounds the whole valve. The papillary muscles, through the chordae tendineae, are inserted into the free edge of the leaflets.

Ventricular systole distends the leaflets like two parachutes. Their free edges approximate, preventing the return of blood into the left atrium. The papillary muscles and the chordae tendineae prevent the leaflets from blowing back into the atrium, and the aortic leaflets guide the blood into the aorta. Valve adjustments are made by contraction of the papillary muscles and by the mitral annulus. The mitral

stenotic mitral valve:

Fig 260.—Mitral stenosis. Note fusion of leaflets along commissures, resulting in enlargement of left atrium (From Vineberg, A., Gialloredo, O., and Laberge, J., in Thorek, Max. Surgical Errors and Safeguards, ed 6, Philadelphia, J B Lippincott Co)

damaged in 34% and the aortic valve alone in 24%. Tricuspid involvement never occurred as a solitary lesion, and combined aortic and mitral disease occurred in 38%.

Valvular Stenoses

Mitral Stenosis

Anatomy.—The mitral valve, between the left atrium and left ventricle, is composed of two leaflets, the larger, anterior septal or aortic leaflet, and the lesser, posterior or mural

valve is thus similar to the human lips, when open it is conical, when closed, slitlike in shape.

Pathology.—The sequence of events which leads to mitral stenosis is not too clearly understood. It is postulated that during acute rheumatic fever, vegetations involve all points of contact of the leaflet surfaces.

Magarey feels that these irregularities cause blood eddies which may initiate further deposits of fibrin, thus explaining the gradual thickening of the valve leaflets and narrow

ing of the aperture that occurs over the intervening years.

The suggestion that mitral stenosis may develop without an initiating attack of rheumatic fever received support from the fact that 7% of normal valve leaflets have fibrin deposits. Further, 45% of patients operated upon for mitral stenosis give no history of rheumatic disease and 5% a history of scarlet fever.

Prior to leaflet edge fusion the commissures are only present when the valve leaflets are approximated during systole. Disease fuses the leaflets, forming true lateral and medial commissures. The mitral orifice may be reduced to 3-5 mm in diameter from its normal size of 1.5-2 cm. Fusion and shortening of the chordae tendineae may form subvalvular stenosis.

Changes in the papillary muscle, chordae tendineae, and valve leaflets which prevent accurate valve closure may produce an associated mitral insufficiency.

Physiopathology.—A narrowed mitral valve interferes with the free passage of blood from the left atrium to the left ventricle. The pressure in the left atrium increases, as does that in the pulmonary vessels and right heart. The strain thrown upon the left atrium causes hypertrophy, progressing to dilatation in most cases. The left ventricle receives less blood and becomes smaller, and the systemic blood pressure tends to be low. The back pressure in the pulmonary arteriolar bed may be reflected as pulmonary edema or hemoptysis. This pressure usually causes enlargement of the pulmonary artery. The right ventricle, pumping against increased resistance hypertrophies, may fail. Right ventricular failure may lead to functional tricuspid valve insufficiency and its sequelae.

Atrial fibrillation increases the pooling of blood in the atria and favors the formation of thrombi in right and left atria and particularly in the left atrial appendage. These may be dislodged to embolize to the brain, other viscera, and extremities. Thrombi leaving the right atrium cause pulmonary infarction. It must be remembered, however, that in advanced mitral stenosis, pulmonary emboli originate more often from the stagnant peripheral veins.

Clinical Picture.—Only about 50% of the patients will give a history of rheumatic fever. The cardinal symptom of mitral stenosis is dyspnea. This changes, as the disease progresses, from mild dyspnea on exertion to severe orthopnea. Hemoptysis, varying from blood-tinged sputum to pulmonary apoplexy, and pulmonary edema are common. Frequently there are repeated episodes of bronchitis and bronchopneumonia. There may be precordial soreness or pain and in the older patients, pain similar to angina pectoris.

Systemic embolism is seen in 9-14% of the cases, of which 60% are to the brain. The right ventricle may fail, and edema and swelling of the abdomen may become the predominant signs.

Physical examination reveals a rumbling diastolic murmur at the apex, a loud M_1 , and an opening snap. P_2 may be accentuated. Peripheral cyanosis and mitral facies, small radial pulse, and mitral thrill are usually present. Examination for evidence of ventricular failure should be made. Atrial fibrillation is common.

The pulmonary circulation time is usually prolonged, but its determination adds little to the diagnosis.

X-ray usually reveals the typical mitral pattern. Fluoroscopy shows more clearly the enlarged left atrium, pulmonary artery, and right ventricle. Pulmonary congestion, a hypodynamic left ventricle, and calcification of the valve may also be seen. A large or giant left atrium, particularly with left ventricular enlargement, indicates mitral insufficiency rather than stenosis.

The electrocardiogram will show right axis deviation in about 80% of the patients with pure mitral stenosis. A prominent P mitral and a right ventricular strain pattern, when present, point to the diagnosis.

Differential Diagnosis.—Classical mitral stenosis offers little difficulty in diagnosis. The diagnostic problem is more that of the detection of associated mitral insufficiency, the presence of other valve lesions, and the evaluation of the state of the ventricular myocardium. Certain conditions, however, must be excluded when mitral stenosis is not entirely typical.

Mitral insufficiency may be pure or associated with stenosis. When both lesions are present it is often difficult to determine which one predominates. Left heart catheterization has not been of sufficient diagnostic help nor has visualization of retrograde flow of radio-paque media. New techniques in dye-dilution studies, at present under trial, may hold the answer to this problem.

Essential pulmonary hypertension characteristically has right heart strain, an enlarged pulmonary artery, but a small left atrium. Right heart catheterization and study of pulmonary capillary pressures will help to differentiate this condition. Pulmonary capillary pressures are minimal in essential pulmonary hypertension and elevated in mitral disease.

Tumors of the left atrium when pedunculated may cause intermittent obstruction of the valve and moderate atrial enlargement. Often symptoms are improved when the patient lies down, as the tumor falls out of the valve orifice.

Cor triatrium. Occlusion of 50% or more of the pulmonary veins will give all the symptoms and signs of mitral stenosis except for enlargement of the left atrium.

Surgical Procedures.—The scope of medical management of mitral stenosis is constantly being redefined as surgical techniques improve. There are, no doubt, a number of patients with narrowed mitral valves who may live for many years with adequate medical treatment, and some may do so with little or no restriction of normal activity. In the majority of cases, the strain imposed upon the heart is cumulative, and eventually, as work tolerance is decreased, the patient may become totally incapacitated. Surgical intervention, to be of the greatest value, must be undertaken before irreversible pulmonary and cardiac changes have developed.

MITRAL COMMISSUROTOMY Indications

- 1 Exertional dyspnea
- 2 Hemoptysis
- 3 Progressive fatigue
- 4 Periphereal embolization
- 5 Auricular fibrillation
- 6 Repeated attacks of bronchopneumonia
- 7 Pregnancy, when previous pregnancy associated with a break in cardiac compensation

- 8 Cardiac enlargement, evidence of right heart strain
- 9 Associated stenosis of aortic, tricuspid, and rarely, pulmonic valves
- 10 Associated valve insufficiency of.
Aortic, slight
Pulmonic, slight
Tricuspid, marked, functional

Contraindications

- 1 Left ventricular failure
- 2 Rheumatic disease activity
- 3 Uncontrolled right ventricular failure
- 4 Recent peripheral embolization (await stabilization and full recovery)
- 5 Uncontrolled aortic irregularities (await proper digitalization)
- 6 Blood volume elevated 15% or more above normal to be corrected
- 7 Associated marked valve insufficiency of:
Mitral
Aortic
Tricuspid

PRINCIPLES.—The reconstitution, so far as possible, of valve function is carried out by (1) separating the fused aortic and mitral leaflets in the lateral and medial commissures, (2) sorting out fused chordae tendineae, and (3) dividing, if necessary, fused papillary muscles.

TECHNIQUE.—The thorax is opened through a left anterolateral or posterolateral intercostal incision and the pericardium opened parallel to the phrenic nerve. A purse-string suture is placed around the base of the left atrial appendage, which is then incised and the right index finger inserted into the atrium. After careful exploration and assessment of the valve mechanism, the mitral orifice is enlarged by fracturing the fused lateral commissure, followed by the medial commissure. This is *digital commissurotomy* or *finger fracture*. In the majority of cases it is necessary to use a knife to start or complete the fracture.

Chordae tendineae are separated when fused and papillary muscles cut to correct subvalvular stenosis. When the valve orifice has been increased in diameter to 2-2½ fingerbreadths, the leaflets usually function well, unless they are heavily scarred or calcified. During actual fracture it is customary to have the anesthetist occlude both carotids in an effort to decrease the possibility of cerebral embolism.

Fig. 261—A, Mitral commissurotomy through the left atrium (From Vaneberg, A., Gialloredo, O., and Laberge, J., in Thorek, Max, *Surgical Errors and Safeguards*, ed. 6, Philadelphia, J. B. Lippincott Co.)

B and C, Case of Grade IV mitral stenosis before (B) and after (C) mitral commissurotomy. Note decrease in size of pulmonary artery and clearing of lung field

The approach through the left atrial appendage is the easiest and most commonly used. However, Bailey advocates entering the thorax through the 4th right anterior intercostal space and the left atrium in the interatrial groove. He claims that the right-sided atrial groove permits exploration of the tricuspid valve which is sometimes involved, the treatment, if necessary, of aortic stenosis, and, finally, better access to the medial commissure. Further, in certain cases due to scar, calcification, or previous operations, the left atrial appendage is too small to enter. The disadvantages of this right-sided approach are that it is more difficult and dangerous technically, and in addition the surgeon is unable to remove thrombi in the left atrial appendage.

COMPLICATIONS.—

Operative.—

Peripheral embolization Thrombi may be dislodged from the atrial appendage or aortic wall. These should be removed before inserting the finger. Emboli also originate from calcified particles released at the time of commissurotomy.

Production of mitral insufficiency. This may occur when the correct line of fracture is missed and a leaflet is damaged, or when chordae tendineae or papillary muscles are accidentally cut.

Tear of the atrial or left ventricular wall. This results in severe blood loss.

Damage to circumflex branch of left coronary artery.

Cardiac arrest.

normal aortic valve:

aortic stenosis

calcified aortic stenosis

Fig 262A-D—A. Aortic stenosis (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thornt, Max Surgical Errors and Safeguards, ed 6, Philadelphia, J B Lippincott Co)

Postoperative.—

1. Pulmonary edema
2. Pericardial and pleural fluid
3. Pneumonia, empyema, and septicemia
4. Peripheral embolization
5. Secondary hemorrhage
6. Electrolyte imbalance
7. Cardiac irregularity
8. Postcommisurotomy syndrome
9. True flare-up of rheumatic fever
10. Late recurrence of mitral stenosis

RESULTS—The results of mitral commissurotomy are influenced by the following:

1. *Extent of mitral commissurotomy*—the character of the valve at the time of operation and the skill and experience of the surgeon

2. *Presence of other valvular disease*, aortic or tricuspid

3. *Degree of irreversible damage* to the myocardium and pulmonary arterioles

DISCUSSION.—In a minority of cases, the chordae and papillary muscles are so altered that it is anatomically impossible to obtain by any means, short of valve substitution, a satisfactory functioning mitral valve. Bailey reports that in his first 1,200 cases there was, in addition to fusion of the commissures, a 20% incidence of a significant degree of sub-valvular obstruction, due to a complex inter-fusion of the chordopapillary supporting tissues

He reports that 65-75% of 1,000 patients treated by mitral commissurotomy and followed up to 8 years have experienced long-term benefit. There were 7.7% operative deaths and a 5.8% late mortality. Of the original 1,000, 71.1% (89.8% of the sur-

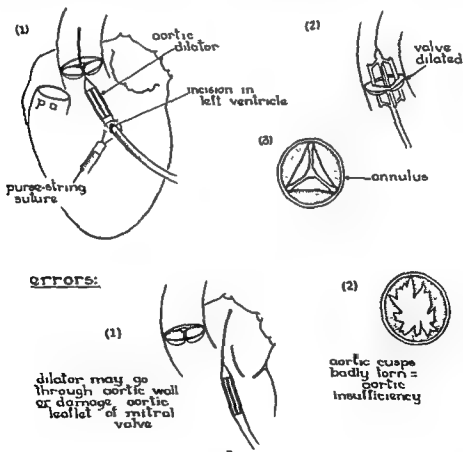

Fig 262 (cont'd)—Aortic stenosis B, Indirect (transventricular) approach for aortic commissurotomy (From Vaneberg, A, Gialloredo, O, and Laberge, J, in Thorek, Max Surgical Errors and Safeguards, ed III, Philadelphia, J B Lippincott Co)

vivors) were improved, 6.2% were the same, and 4% were worse. Roughly, 10-15% of the patients are not helped by operation. Many poor results were due to inadequate commissurotomy and failure to detect and correct associated lesions of the other valves.

Aortic Stenosis

Definition.—The term aortic stenosis has been used clinically to imply narrowing the outflow tract of the left ventricle. In many instances this is caused by disease of aortic valve, but occasionally it may be due to

Fig. 262 (cont'd) —Aortic stenosis C. Indirect (supra-aortic) approach for aortic commissurotomy. (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max: *Surgical Errors and Safeguards*, ed. 6, Philadelphia, J. B. Lippincott Co.)

to a congenital condition involving the sub-valvular region.

Incidence.—Acquired aortic stenosis comprises 40% of all deformities of the valves and occurs in a ratio of 4:1 in the male. The average age of death is 45 to 50 years, being approximately 15 years later than that of mitral stenosis.

Etiology.—Two different causes are given for acquired aortic valvular stenosis: rheumatic valvulitis, considered to be the more frequent cause, and aortic valvular sclerosis, said to be the degenerative disease (Mönckeberg).

Anatomy.—The aortic valve is formed by three semilunar-shaped cusps, attached peripherally to the aortic ring. During ventricular systole the ejected blood flattens the cusps against the aortic wall, during diastole they fall back to meet in the center, preventing the return of blood to the ventricle. There are three commissures: the anterior, which is in

line with the posterior commissure of the pulmonary valve, and a right and a left posterolateral. Each cusp, when distended, forms a sinus (Valsalva) between itself and the aortic wall. The two main coronary arteries arise from the two anterior sinuses. No artery leaves from the posterior sinus.

Pathology.—The state of the valve in acquired disease may be classified as follows:

Fusion of commissures with intact cusps. The valve leaflets are still intact and pliable, and the obstructive effect is caused mainly by the fusion of the commissures. This group gives the best results following surgery.

Fusion of commissures with damaged cusps. In addition to interfusion, the cusps are thickened, scarred, wholly or partially calcified, and may be retracted to cause an associated insufficiency. Such valves, despite adequate surgical separation of the fused commissures, may give poor functional results.

Fig. 262 (cont'd)—Aortic stenosis. D, Direct approach for aortic commissurotomy (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max. *Surgical Errors and Safeguards*, ed 6, Philadelphia, J. B. Lippincott Co.)

The electrocardiogram shows left axis deviation or left ventricular strain. When marked mitral stenosis is present, a mid or right axis deviation may be seen.

The pressure gradient across the aortic valve may be measured (see cardiac catheterization). A gradient of 40 mm. Hg or more indicates marked stenosis, and surgery is warranted. Concomitant mitral stenosis and failing myocardium, however, can produce a small pressure gradient, despite severe aortic stenosis.

In those patients with rheumatic aortic valvulitis, the commissures are generally solidly fused, and if the valve cusps are not too thick and rigid, opening of the commissures favors cusp action and at least removes the obstruction to forward blood flow. When there is marked calcification of the valve cusps, opening of the commissures may result in little relief of aortic stenosis since the rigid cusps fail to yield during systole, in the same way as do the nonfused arteriosclerotic cusps.

SURGICAL METHODS OF AORTIC COMMUNICATION.

SURGICAL METHODS OF VALVULOTOMY—
The Transventricular Route.—A valvulotome and dilator are passed through a small incision in the left ventricle and into the aortic valve. The main disadvantages of this method are that the valve cannot be palpated, that the procedure is entirely blind, and that ventricular fibrillation frequently occurs when an already irritable myocardium is manipulated. Uncontrollable hemorrhage from the site of ventriculotomy is not uncommon.

Supra-aortic Approach.—An opening is made in the anterolateral surface of the aorta just distal to the valve to which a pouch is sewn. Through this pouch the index finger explores the valve and in many instances opens it. In other instances the commissures have to be cut with a knife or forced open with a dilating instrument.

Valvuloplasty Under Direct Vision.—This technique necessitates arrested circulation, either under hypothermia or preferably with

Valvuloplasty Under Direct Vision—This technique necessitates arrested circulation, either under hypothermia or preferably with

a pump-oxygenator. The valve cusps may be accurately separated and trimmed of excessive calcified tissue (as for pulmonic stenosis, see Fig. 246).

RESULTS.—Results of aortic commissurotomy vary according to the severity of the disease and the type of commissurotomy performed. Mortality is about 28% for the transventricular approach and 14% for the transaortic approach. Clinical improvement occurred in over 80% of the survivors

Incidence.—Significant tricuspid stenosis occurs in roughly 6% of cases of mitral stenosis submitted to surgery, and a minor degree of stenosis occurs in another 14%.

Physiopathology.—The pathology is similar to that of mitral stenosis. The right atrial pressure is elevated and causes venous engorgement, hepatomegaly, ascites, and peripheral edema. It must be remembered that this lesion is almost always associated with mitral stenosis and that the obstruction of tricuspid stenosis

Fig. 263A-G—A, Mitral insufficiency (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max Surgical Errors and Safeguards, ed 6, Philadelphia, J. B. Lippincott Co.)

Tricuspid Stenosis

Etiology.—Rheumatic fever is the commonest cause. Isolated tricuspid stenosis is so rare that, if found, other less common causes such as atrial tumor or malignant carcinoid should be suspected.

may mask many of the pulmonary symptoms that characterize mitral disease.

Symptoms.—The symptoms are similar to those for tricuspid insufficiency except for the character of the murmur. The jugular pulse has characteristic giant A waves. Heart catheterization may confirm the diagnosis.

Treatment.—Treatment is similar to that for mitral stenosis, i.e., separation of the fused commissures. Because of its association with other valve lesions, it has been suggested that whenever a mitral commissurotomy is performed, the tricuspid valve should be explored.

Valvular Insufficiency

Unlike valvular stenosis, valvular insufficiency is very difficult to correct surgically. At present there is great doubt as to the value of the numerous surgical procedures devised to treat valvular incompetence.

scarred and retracted that they do not meet properly at the valve closure.

Destroyed Chordopapillary Mechanism.—Rupture of the chordae produces an unstable leaflet that cannot control reflux. Extreme scarring and contraction of chordae may prevent the leaflet from approximating with its mate.

Valvular Stenosis.—Fusion of leaflets may produce a rigid narrow valve, which, in addition to obstructing flow, permits regurgitation.

annular weakness:

partial loss of leaflet substance.

errors:

sutures through leaflet instead of annulus

errors:

3. suture too deep: catches circumflex artery

complete loss of leaflet substance:

B

Fig. 263 (cont'd) —Mitral insufficiency B, Operative treatment, using the extracorporeal circulation (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max: *Surgical Errors and Safeguards*, ed. 6, Philadelphia, J. B. Lippincott Co.)

Pathology.—The following types of lesions may occur alone or in combination.

Stretched Valve Annulus.—Disease of the annulus permits stretching of this structure, causing separation of the leaflets which may be normal. This type is also seen in functional insufficiency.

Loss of Valve Substance.—The annulus may be normal, but the leaflets and cusps are so

Mitral Insufficiency (Regurgitation)

A significant degree of insufficiency has been found in 11% of cases explored for mitral stenosis. The presence of insufficiency materially alters the prognosis for patients undergoing mitral commissurotomy. It is frequently impossible to determine preoperatively whether stenosis or incompetence predominates or which of the mechanisms mentioned above

has caused the insufficiency. Since correction of mitral stenosis may improve certain types of mitral insufficiency, exploratory operation may be justified in doubtful cases.

Clinical Picture.—The picture is similar to that for mitral stenosis but with perhaps fewer respiratory symptoms initially. When deterioration does occur, the downhill course is rapid. A loud systolic murmur radiating from apex to axilla is characteristic. Electrocardiography reveals left ventricular preponderance. Fluoroscopy shows an enlarged left ventricle and a very large or giant left atrium which may have a systolic expansion.

Fig. 263 (cont'd)—Mitral insufficiency

G, Intra-atrial pressure in patient shown in C-F, before and after mitral annuloplasty. Note the reduction in average systolic pressure in the left atrium.

Treatment.—Numerous operations have been devised and most of them discarded. Three techniques under evaluation at the present time seem promising. Unfortunately they all have two points in common, i.e., a high mortality and equivocal results.

Circumferential Tape Suture.—The annulus may be constricted by suturing an umbilical tape circumferentially around the left arterio-venous groove. This is tightened until the leaflets meet.

Cross Polar Ligation.—The annulus is constricted by inserting two heavy sutures through

it at its medial end. This is perhaps the best of the closed methods.

Open Reconstruction.—By the use of extra corporeal circulation, the valve is visualized; the leaflet defects are filled with Ivalon sponge and the annulus narrowed. This technique, when perfected may be the treatment of choice.

Aortic Insufficiency

Etiology.—Rheumatic fever is said to cause 67% and syphilitic aortitis 19% of cases presenting aortic insufficiency.

Clinical Pathophysiology.—Blood leaks back into the left ventricle during diastole which, with the blood entering from the left atrium, places an extra load upon the left ventricular fibers. There is a rapid ejection of blood into the aorta during systole with a diastolic fall of aortic pressure. The regurgitation of blood into the left ventricle increases the end diastolic ventricular pressure, making it more difficult for blood to enter the left ventricle from the left atrium. The resulting left atrial hypertension causes pulmonary hypertension.

Clinical Picture.—At first the patient may be asymptomatic, but as left ventricular strain develops there may be paroxysmal attacks of dyspnea, acute pulmonary edema, hemoptysis, and anginal pain. An early blowing diastolic murmur, heard best at the 2nd right intercostal space close to the sternum, is transmitted down the left sternal border; an Austin Flint murmur may be heard at the apex as a mid-late diastolic murmur; a water-hammer pulse, an elevated pulse pressure, and low to no diastolic pressure with capillary pulse are characteristic. In advanced cases the patient's head is often observed to nod with each cardiac beat.

X-ray shows a characteristic bootlike shadow due to enlargement of the left ventricle. Brachial artery tracings are likewise characteristic.

Treatment.—The Hufnagel prosthetic ball valve, placed in the descending aorta beyond the left subclavian artery, is the best treatment now available. The valve relieves the left ventricle of part of its load but fails to protect the coronary or cerebral vessels from the effects of aortic insufficiency. Deaths have been

reported from coronary insufficiency, erosion of the prosthesis through the aorta, and peripheral emboli. This form of treatment is still highly experimental

Multiple Valve Lesions

Rheumatic fever may involve all four heart valves, either singly or in combination. Autopsy studies show that disease (stenosis, insufficiency, or both) may involve the valves with the following frequency: aortic and mitral 19.2%; aortic, mitral, and tricuspid 11%; mitral and tricuspid 2.9%; pulmonary and tricuspid 1%, all four valves 1%.

Mitral and Aortic Stenosis

Mitral stenosis has been reported by Bailey to occur in 38% of patients with aortic stenosis, or 15% of all acquired valvular disease.

Physiopathology.—The obstruction of the mitral valve decreases the flow of blood into the left ventricle and masks the signs of aortic stenosis. The elevated left ventricular diastolic pressure augments the effect and may even intensify the picture of mitral stenosis. The pressure gradient across the aortic valve may be low because of the protective effect of the mitral stenosis, and the unwary clinician may underestimate the severity of the aortic valve lesion.

Diagnosis.—The characteristic signs and symptoms of each lesion are present in a greater or lesser degree. The ECG may show preponderance of either ventricle but more often of the right. Left heart catheterization and measurement of the pressure gradients between the valves will confirm the diagnosis.

Surgical Treatment.—At present, closed techniques seem to give the best results. The following approaches may be used:

1 *Vertical sternal splitting incision* gives adequate access to the aortic valve but makes mitral valvotomy difficult.

2 *A left anterolateral thoracotomy* is excellent for the mitral valve and permits transventricular aortic valvotomy.

3 *A right anterolateral thoracotomy*, while good for the transaortic valvotomy, necessitates approaching the mitral valve through the inter-

atrial sulcus. The tricuspid valve is easily explored if indicated.

4. *Bilateral anterior thoracotomy with division of sternum* gives adequate exposure for all valves and permits any technique of valvotomy desired.

Whatever the approach, the aortic valve is first opened, following the principle of first relieving distal obstruction. The mitral commissurotomy may then be performed when the heart has stabilized.

The results are surprisingly good following commissurotomy of both valves. Mortality is about 18%, and 31% of the patients are markedly improved and 51% improved. Objective evidence of the adequacy of valvotomy may be obtained by taking cross-valve pressure recordings several months postoperatively.

Mitral and Tricuspid Stenosis

Incidence.—Tricuspid stenosis is said to occur in about 20% of cases of mitral stenosis, although in only 6% is the stenosis severe. In general, results of commissurotomy for combined mitral and tricuspid stenosis are most satisfactory.

CORONARY ARTERY HEART DISEASE

Definition.—This is an acquired disease caused by arteriosclerotic narrowing or occlusion of the coronary arteries. A distinction should be made between the terms *coronary artery disease*, in which only the coronary arteries are diseased, and *coronary artery heart disease*, in which both coronary arteries and the myocardium are involved.

Incidence.—Heart disease is the leading killer in the United States. In 1953, 65% of the 566,420 persons dying from heart disease had arteriosclerosis as the basic cause. At autopsy, 1 of every 4 hearts showed evidence of coronary artery disease and 1 in 10, of infarction. Males predominate 4:1.

Anatomy

The main coronary arteries arise from the aorta in the sinuses of Valsalva and branch over the right and left heart to form a corona. The major branches are on the surface and can readily be seen pulsating. The branches of the coronary arteries penetrate the myocardium and form four arteriolar zones. In

Fig 264.—Diagrammatic representation of coronary circulation showing its complexities

Fig 265.—A, Arteriolar zones in the normal heart. Note absence of collaterals
B, Arteriolar zones in the diseased heart. Note presence of collaterals

normal hearts these arteriolar networks do not usually communicate. In addition there is some evidence to suggest that an individual spiral muscle is supplied by its own arterial branch.

The majority of arterioles end in capillaries which surround and supply the muscle fibers. Some, the arteriololuminal, by-pass the capillary system and communicate directly with the cardiac chambers. Others, the arteriosinusoidal, join the myocardial sinusoids lying between the muscle bundles. These large endothelial-lined spaces communicate with the arteriolar system and with the capillaries surrounding the muscle fibers.

Only 60% of the arterial blood entering the myocardium is recovered from the coronary sinus. The remainder is believed to reach the heart chambers by anterior cardiac veins and thebesian canals. The thebesian canals are venouslike spaces joining the capillary systems and ventricular lumina.

Extracardiac Sources of Blood.—There are capillary communications between the vessels supplying the pericardium and the coronary circulation. These are small and functionally insignificant. The coronary arterial flow is influenced by differences in pressure in the aorta and in the myocardial arteriolar network. A lowered aortic diastolic pressure markedly decreases the rate of coronary flow. Further the differences in pressure between one arteriolar zone and another seem to favor the formation of intercoronary anastomoses.

Pathology

Arteriosclerosis when it occurs is usually in the first 3-5 cm. of the coronary vessels and is generally confined to the epicardial portions. The vast myocardial arteriolar network is, for the most part, disease free. Normally, there is no communication between the four arteriolar zones. However, when ischemia develops, intercoronary anastomoses open up to form collaterals.

The fate of an ischemic zone depends on (1) the size of the vessel involved, (2) the rate of narrowing of the supplying coronary artery, (3) the rate of development of col-

laterals, and (4) the demand of the ischemic area for oxygenated blood.

Acute Myocardial Infarction.—Sudden occlusion or narrowing of a large or even small vessel may result in death from cardiac arrest. Survival of the patient is almost always accompanied by infarction of the ischemic myocardial area. There appear to be two main types of acute myocardial infarction: one which involves the whole thickness of the ventricular muscle, and the other, a laminated area of necrosis. In the latter type there may be a healthy zone of muscle on the surface. In general, an interval of six weeks is required for removal of necrotic muscle and at least six months for the establishment of a collateral circulation.

Chronic Myocardial Infarction.—Slow progressive occlusion of a coronary artery may not result in any myocardial change, providing the pressures in the adjacent arteriolar zones favor the development of arteriolar anastomoses.

Unfortunately, atherosclerosis generally involves more than one major coronary artery, and the good neighbor arteriolar zone is little better off than the affected area. In such cases repeated small losses of muscle fibers may result in the almost complete fibrous replacement of the ventricular myocardium.

Myocardial fiber loss, when gradual, may at first pass unnoticed. Gradually the myocardial reserve is reduced, and eventually the left ventricle dilates and fails. Patients with this condition are beyond help. It is too late once the myocardium has been reduced to scar tissue to obtain benefit from introducing fresh extracardiac sources of blood.

Localized areas of fibrosis may dilate to form ventricular aneurysms.

Angina Pectoris

Angina pectoris is a typical substernal or precordial pain radiating to the left shoulder or arm, initiated by exertion and relieved by rest or nitroglycerin. It was first described by Heberden. The mechanism in the production of anginal pain is not clear. There is general agreement that this symptom reflects myocardial ischemia, usually caused by nar-

rowed coronary arteries. Sustained chest pain, anginal in character, is generally caused by myocardial infarction

Coronary artery disease may be present and be asymptomatic. Likewise coronary artery heart disease may develop to a far-advanced stage with marked myocardial ischemia and destruction, without the patient's experiencing anginal pain.

or the treadmill exercise may leave the diagnosis in doubt. Unfortunately most observers do not live long enough to learn from pathologic studies the true effect of a given treatment in the alleviation of a chronic disease.

Surgery of Coronary Artery Heart Disease

During the past 50 years many attempts have been made by surgeons to help their

Fig 266—Illustration of various operative procedures for the treatment of coronary artery heart disease

Chest pains that are not initiated by physical activity or emotion, are of long duration, and do not disappear quickly with rest or nitroglycerin are not caused by myocardial ischemia and should be regarded with suspicion. A search for hiatus hernia, biliary tract disease, peptic ulcer, cervical or upper thoracic discs, and neurosis may disclose the source of the patient's pain. The electrocardiogram is of value when it is positive. Failure to obtain ECG evidence of coronary artery disease with the Master's two-step test

medical colleagues in the treatment of coronary artery heart disease. The following surgical procedures have been attempted:

- 1 Neurosurgery to interrupt afferent pain paths
- 2 Reduction of thyroid function
- 3 Development of collaterals and/or anastomoses
 - a Ligation of cardiac vein
 - b Ligation of coronary sinus
 - c Bilateral internal mammary artery ligation
- 4 Direct attack on diseased coronary arteries
 - a Resection and graft substitution of occluded coronary artery
 - b Endarterectomy

- 5 Myocardial vascularization by extracardiac blood
- Surface grafts applied to the heart: pectoral muscle, omentum, lung, pericardial fat pad, skin, jejunum
 - Cardiopercardiopexy (pericardial poudrage), bone chips, asbestos, talc
 - Ventricular arterialization by vascular implants
 - Internal mammary artery implant
 - Splenic artery implant
 - Carotid artery implant, or
 - Graft from aorta to myocardium

procedure frequently relieves anginal pain but fails to improve myocardial ischemia.

The concept of reducing the demands of the heart by causing hypothyroidism is badly founded. The progress of the disease is not arrested and may be increased. The failure of this method to increase the blood supply to the heart explains why there is no improvement in the patient's exercise tolerance.

Fig. 267A C —Beck I operation for coronary artery insufficiency

A, Partial ligation of coronary sinus (From Vineberg, A., Gialloreti, O., and Laberge, J., in Thorek, Max: *Surgical Errors and Safeguards*, ed 6, Philadelphia, J B Lippincott Co.)

There are four objectives for surgery in the treatment of coronary artery heart disease (1) to relieve angina pectoris, (2) to increase exercise tolerance and ability to work, (3) to prevent further loss of myocardial fibers, and (4) to prolong life expectancy.

Neurosurgery is carried out at times to block afferent pathways of cardiac pain. This

The encouragement of the development of collaterals should not be considered a basic treatment but part of a procedure which distributes arterial blood to the heart without introducing extracardiac blood.

Coronary artery resection and endarterectomy are procedures that are still highly experimental.

Surgical revascularization methods attempt to by-pass points of coronary artery obstruction by introducing an extracardiac source of blood to the intact ventricular arteriolar zones. In practice, the development of channels which carry a volume of blood sufficiently large to relieve myocardial ischemia is difficult. The following three methods are in current use.

tion of coronary sinus to promote intercoronary anastomoses, (b) removal of epicardium and sprinkling with irritating asbestos powder over the left ventricle, (c) application of pericardial fat pad grafts to the surface of the left ventricle. This operation has been shown experimentally to distribute blood evenly throughout the myocardium.

Fig 267 (cont'd).—Beck I operation for coronary artery insufficiency.

B, Pericardium and epicardium scraped

C, Pericardio-cardioplexy.

(From Vineberg, A, Gialloreti, O, and Laberge, J, in Thorek, Max: *Surgical Errors and Safeguards*, ed 6, Philadelphia, J. B. Lippincott Co)

1. **Cardiopericardioplexy.**—In this operation the left 6th intercostal cartilage is removed, the pericardium is opened, and talc powder is introduced into the pericardial sac. This procedure forms granulomatous adhesions between the serous layers.

2. **Beck I Operation.**—The Beck I operation is performed as follows: (a) partial liga-

3. **The Vineberg Internal Mammary Artery Implantation.**—(a) The left internal mammary artery is detached from the chest wall, (b) The internal mammary artery is pulled into a left ventricular tunnel after the 6th intercostal artery has been severed, thus leaving an open bleeding vessel in the myocardium. (c) Supplementary fat pads are

sewn to the surface of the left ventricle after the removal of the epicardium by sharp dissection.

With regard to the Vineberg operation it has been proved experimentally that the internal mammary artery remains open after implantation into the ischemic myocardium because it bleeds into the myocardial sinusoids. Within 12 days it branches to form true

arterioles, which later join with the arterioles within the heart muscle. The amount of arteriolar blood delivered is sufficient to prevent death or infarction in the experimental animal subjected to coronary artery occlusion. Further, the artery has been shown to remain open with little or no intimal proliferation in both animal and man when examined up to 3½ years after implantation.

Fig. 268.—The Vineberg internal mammary artery implant operation for the treatment of coronary artery insufficiency (From Vineberg, A., Gialloredo, O., and Laberge, J., in Thorek, Max Surgical Errors and Safeguards, ed. 6, Philadelphia, J. B. Lippincott Co.)

Recently, using the principle of internal mammary artery implantation, a few patients with coronary artery heart disease have been treated by inserting a nylon tube graft from the aorta into the left ventricular wall. Italian workers, utilizing the same principle, have placed a polyethylene T tube into the left ventricle, joining the left ventricular lumen to the myocardial sinusoidal system.

Selection of Patients for Remedial Surgery.—This should be largely dependent on the stage of development of the patient's disease, and the following criteria are suggested

CONTRAINDICATIONS FOR SURGERY.—

1. Asymptomatic coronary artery disease. This view, as mentioned, is not shared by all.
2. Recent infarction or evidence of disease activity. A period of 6 months should elapse after infarction before surgery is considered.
3. Marked enlargement of the left ventricle. The enlarged left ventricle may represent dilatation due to failure, hypertrophy due to hypertension, or a combination of both, with marked scar replacement. Such ventricles are beyond help; so much damage has been done to the myocardial fibers that they are either

Fig 269.—Implanted internal mammary artery bleeding into myocardial sinusoid

INDICATIONS FOR SURGERY.—

1. There must be proved coronary artery heart disease with typical angina pectoris. Patients who have angina at rest are acceptable for surgery, provided there is an exciting cause.
2. Failure of angina to improve on medical treatment over a period of 1-2 years.
3. Two coronary occlusions with myocardial infarctions. Patients who have had two or more coronary artery occlusions with infarction, even though asymptomatic, have such a poor outlook for survival that some cardiologists are of the opinion that these should be accepted for surgery.

beyond restitution or have been replaced by scar tissue. No revascularization procedure can benefit such a heart any more than a femoral artery graft can revive a gangrenous leg.

4. Rapid progressive deterioration. With this group of patients many surgeons prefer to wait for some degree of stabilization. Not infrequently the accentuation of anginal pain may be a precursor of coronary artery thrombosis and infarction. Such patients may die in the anesthetic room, on the operating table, or shortly thereafter, from an exacerbation of their disease.
5. Malignant hypertension, severe diabetes, and other incurable diseases.

Fig 270.—Photomicrographs of human internal mammary artery 18 months after implantation. Patient was completely relieved of symptoms following operation and died of cancer of the pancreas. Inferior mammary artery in myocardial tunnel. A, At beginning of tunnel (flattened due to preservation of specimen). Note patent lumen and absence of intimal proliferation. B, One third of the way along tunnel. Observe extensive branching of artery which has been filled with India ink injected antigrade into left circumflex coronary artery. C, Two thirds of the way along tunnel. Artery still branching. D, Close to exit of tunnel. Artery still patent and branching. Note extensive fibrosis throughout the myocardium.

6 The angina decubitus group, i.e., patients who have angina at rest without exciting cause. Those who experience night pain or pain at rest while watching television or after eating do not necessarily have angina decubitus. Patients who have true angina decubitus should not undergo revascularization surgery because the mortality risk is high, and the end results are poor in those who survive operation.

RESULTS OF TREATMENT.—The recent report of Richards et al on a 25-year follow-up of cases of myocardial infarction can be used as a guide in the selection of patients for revascularization surgery. To quote these authors: "The best index to long term prognosis following myocardial infarction is the degree of recovery of the patient following the acute period of infarction." In their patients who had complete medical recovery following infarction, 82% were alive at the end of 5 years, whereas the longevity for the entire group of 162 cases was 49% 5 years after myocardial infarction.

Although patients with angina pectoris without infarction appear to have a better future, White states that angina pectoris implies a continuous mortality which is essentially constant and is usually 7% above that expected. The asymptomatic patient therefore has a good prognosis, his myocardium being well supplied with blood by undiseased collateral arteries, which are known to send collaterals to the ischemic zone so that there is no need for extracardiac sources of blood. Any type of revascularization surgery upon such patients can do no more than Nature has already done.

The treatment of coronary artery disease is probably one of the most difficult to evaluate because of the numerous and unpredictable variations which occur during its natural course. This is true for both medical and surgical therapy. The comparison of individual cases is difficult, but not so with those cases which fit into a certain broad classification. Thus, in evaluating the results of surgery for coronary artery heart disease, there has to be a certain basic classification of cases for comparative purposes.

There are two main groups of patients in whom entirely different results may be expected from revascularization surgery. (1) pa-

tients with angina decubitus, i.e., those who suffer angina at rest without exciting cause, and (2) patients with no angina at rest. Until objective radiologic and other evidence of improved myocardial circulation after surgery is available, the observer must, of necessity, rely upon the following criteria: (1) survival, (2) disappearance of anginal pain for more than 6 months; increase in work and exercise tolerance, (3) improvement in the electrocardiogram, and (4) failure to develop fresh infarction.

Survival.—This pertains to both postoperative and long-term survival. A postoperative death is one that occurs from any cause within 30 days of operation (A.C.S. definition).

Anginal Pain.—Pain is subjective and thus very difficult to estimate both before and after operation. For this reason our patients are seen by two cardiologists and a psychiatrist. Certainly the disappearance of anginal pain a few days or even a few weeks after any surgical revascularization procedure may be on a psychologic basis. Experience indicates that evaluation of an operative procedure should not be made under 6 months. It is again stressed that a careful record be made of the patient's ability to work and exercise without pain before operation. The Master's two-step test and the treadmill give a dependable estimate of the patient's ability to exercise.

Electrocardiogram.—The results obtained by ECG studies leave much to be desired. Too much reliance should not be placed on the ECG in either direction in estimating postoperative improvement.

Failure to Develop Fresh Infarction.—Revascularization surgery does not alter the predetermined course of coronary artery disease except to prevent myocardial fiber loss.

Evidence is now accumulating to indicate that coronary artery occlusion may occur without evidence of myocardial infarction following a satisfactory revascularization. This appears to have been true in at least five postoperative internal mammary artery implantation cases.

There are two operations in use in the treatment of human coronary artery heart disease which have a most extensive experimental background and a long period of clinical trial

These are (1) Beck I operation; (2) internal mammary artery implantation of Vineberg.

The Beck I operation has a mortality rate of 63%, and 80% are markedly improved. Unfortunately there are no published figures indicating the type of patient operated upon, thus making a division into the cases with far-advanced angina decubitus and those without anginal pain at rest impossible at the present time. The over-all low mortality and good postoperative results are most impressive.

Vineberg and Walker have recently reported their results in 88 patients with coronary artery heart disease treated by internal mammary artery implantation. The over-all mortality rate in the combined series for those patients who had no angina at rest was 5.8% and for those patients who suffered from angina decubitus, 40%. There were 20 patients with angina decubitus in this group of whom 60% survived the operation. Only 35% showed no pain or less pain, and 30% of the completely disabled group returned to work.

In the group of 68 patients who had no angina at rest, 72% were totally disabled prior to operation. The group was followed from 6 months to 6 years, 78% had no pain or less pain, with 79% having returned to work.

THORACIC ANEURYSMS

Definition.—An aneurysm is a bulging due to a local defect of the arterial wall. If the arterial weakness involves the whole circumference, the aneurysm is fusiform, if only part of the circumference is involved, it is saccular.

Etiology.—The causes are (1) arteriosclerosis, (2) syphilis, (3) rheumatic fever, (4) poststenotic dilatation, (5) trauma, (6) mycotic infection, (7) dissecting process, (8) congenital defect.

Aneurysms may appear anywhere in the aorta or great vessels, from the origin of the coronary arteries onward. Most aneurysms of the ascending aorta are syphilitic. Aneurysms may also be congenital, and these are occasionally multiple. In coarctation of the aorta there may be poststenotic dilatation, which sometimes becomes aneurysmal. In addition there may be smaller aneurysms of the inter-

costal vessels due to the high flow through them in this disease. Aneurysms may follow trauma, such as is seen when a penetrating foreign body may graze and so weaken a portion of the arterial wall. Violent nonpenetrating trauma may produce a tear in the vessel wall which will later become aneurysmal. Most thoracic aneurysms, however, result from arteriosclerosis. Whatever the cause, aneurysms dilate relentlessly until they rupture. (See also Chapter 33.)

Clinical Picture.—An enlarging intrathoracic mass may produce symptoms from pressure. Pressure on the tracheobronchial tree may cause atelectasis and a tracheal tug, that on the esophagus may produce dysphagia, and that on the adjacent nerves, a Horner's syndrome and vocal cord paralysis. The aneurysm may erode bone and produce severe pain. Thrombosis and vessel distortion may cause differences in peripheral pulses.

X-ray and fluoroscopy suggest the diagnosis by revealing a mass in relation to the aorta which may pulsate. In certain cases bronchoscopy may show tracheal or bronchial compression. Visualization of the aneurysm is possible by retrograde aortography or angiocardioradiography.

Treatment.—The treatment of aneurysms of the thoracic aorta is surgical excision. Two types of procedures may be employed, depending on the type of aneurysm. Saccular aneurysms may be excised distal to a clamp placed across the neck, the aorta being repaired without encroachment on its lumen. More extensive aneurysms require resection of a segment of aorta and replacement by aortic homograft or plastic prosthesis. The latter procedure requires temporary interruption of aortic flow. The absence of collateral channels prohibits prolonged aortic occlusion because of the danger of damage to brain and spinal cord. Ischemic damage to the kidneys occurs but is not as significant as the cord damage. In either case the damage increases in proportion to the length of aorta that must be excluded by clamps.

To avoid these complications, a temporary path for blood flow must be created with vessel grafts or plastic tubes, or metabolism of the vital centers may be reduced by hypo-

FIG 271 —Heart tumor, left atrium

B, Patient in supine position is, paradoxically, relieved of dyspnea as tumor falls away from mitral valve

Fig 272 —Composite diagram showing four types of sympathectomy used in the treatment of essential hypertension

thermia. Extracorporeal circulation is necessary for resection of the ascending aorta.

Dissecting Aneurysm

This condition results from the passage of blood through a tear in the intima and media of the aorta. Usually it arises in the ascending aorta and is due to arteriosclerosis. The blood pressure forces the blood between the layers of the aortic wall, so that the dissection may proceed down to the bifurcation. The intramural passage may rupture outward and exsanguinate the patient, or it may rupture back into the aortic lumen, a condition compatible with life but unfortunately less common than the first alternative.

Treatment.—However, this communication between the dissecting aneurysm and the aortic lumen may be produced surgically. All layers of the aorta involved by the dissecting process are divided between clamps. The inner and outer walls of the proximal segment are sutured together for part of the circumference and a wedge portion removed from the inner tube. The inner and outer walls of the distal portion are sutured together and then anastomosed to the proximal segment (See Plates 52 and 53 and Chapter 33).

TUMORS OF THE HEART

Pathology.—Primary tumors are rare, atrial myxoma being the commonest. Fibroma of the ventricular wall and sarcomas filling the cardiac chambers are less common. Rhabdomyoma may be multiple and occasionally is associated with tuberous sclerosis.

Secondary tumors are not infrequent, occurring in some 10% of malignancy cases at post mortem, although they are symptomatic in less than 1%. Leukemic infiltration does occur but is uncommon.

Clinical Picture.—The symptomatology is bizarre, and the diagnosis is rarely made preoperatively. As many of the tumors arise in the atrium and are pedunculated, atypical signs of mitral or tricuspid stenosis may be seen. These signs may alter on change of body posture. Most laboratory studies afford little help, although angiocardigraphy may show a filling defect.

Treatment.—Although a few atrial myxomas have been enucleated by closed techniques, it seems preferable to do an open cardiomy.

ESSENTIAL HYPERTENSION

The surgical treatment of essential hypertension by sympathectomy has greatly lessened in significance in the last few years. The various procedures used were the subdiaphragmatic, supradiaphragmatic, thoracolumbar, and radical thoracolumbar sympathectomies which are shown in Fig. 272. Bilateral adrenalectomy has also been performed but is such a crippling operation and the results so uncertain that it again is seldom used. This decline in surgical intervention has resulted from advances in the medical management and the further development of medication to control the hypertension.

Certain special conditions such as coarctation of the aorta, pheochromocytoma of the adrenal and unilateral renal disease may be found on the investigation of the hypertension. In such cases, surgery is specifically indicated to obviate the underlying causation.

Esophagus

Darrell D Munro, MD, Edward J. Tabah, M.D. and
H Fred Moseley, DM

INTRODUCTION

Many factors make surgery of the esophagus technically difficult. Some of these are related to anatomic peculiarities. Others have to do with the ordinary problems of intrathoracic surgery, such as control of the open thorax and the maintenance of lung expansion sufficient to ensure adequate oxygenation of the blood. Because of great advances in the field of anesthesiology, the thorax may now be opened with as little risk as the abdomen. However, it was as recently as 1938 that Phemister and Adams were the first to perform a successful one-stage resection of the esophagus and the cardiac portion of the stomach.

APPLIED ANATOMY AND PHYSIOLOGY

The esophagus is a muscular canal which extends from the pharynx to the stomach. Its wall is composed of three layers: an inner mucous membrane, a submucous layer, and an outer muscular layer. Unlike other parts of the gastrointestinal canal, the esophagus has no serosal covering, and this fact has been mainly responsible for the failure of early attempts at resection and esophageal anastomosis. The mucous membrane is of the squamous cell type except for the most distal portion where the cells become columnar in character.

The circular and longitudinal muscle layers of the cervical and upper thoracic portions are composed entirely of voluntary muscle fibers. Below this level there is an increasing proportion of smooth muscle with a corresponding decrease of striated muscle, and, in the lower third, the musculature is entirely involuntary in type.

The main function of the esophagus is to convey fluid and food from the pharynx to the stomach. Food is propelled down the esophagus by peristaltic waves, but fluids descend mainly by gravity. Before food or fluid can enter the stomach, the very terminal portion of the esophagus must relax. Whether a true sphincteric mechanism exists here or not is still controversial. This area is designated the *cardiac sphincter*. The term *cardia* was originally introduced by Galen, who realized that disease in this area could simulate heart disease very closely. The mechanism that opens the sphincter is obscure, but it is dependent on the nerve supply of the esophagus which is derived from the vagi and the sympathetic trunks.

Normally, the esophageal lumen is narrowed at three points: (1) at the level of the cricoid cartilage, (2) where it is crossed by the left bronchus, and (3) where it pierces the diaphragm.

The esophagus is divided into cervical, thoracic, and abdominal portions. The cervical portion begins at the lower border of the cricoid cartilage, opposite the 6th cervical vertebra. Anteriorly, lie the trachea and the thyroid gland, while posteriorly are the vertebral column and the longus colli muscles. The common carotid arteries and part of the lateral thyroid lobes lie on either side of it. Between it and the trachea, the right and left recurrent nerves ascend. The thoracic duct lies to its left side.

portions, and a lower thoracic segment from the root of the lungs to the diaphragm. After entering the thorax, the esophagus rests upon the vertebral column, the longus colli muscles, the right intercostal arteries, the thoracic duct, and the hemiazygos and accessory hemiazygos veins. In front are the trachea, the left main bronchus, pericardium, and diaphragm. On the left side, in the supra-aortic part, lie the left subclavian artery, thoracic duct, and the left pleura, with the left recurrent laryngeal nerve between the trachea and the

Fig. 273—Segmental arterial blood supply of the esophagus

The thoracic portion begins at the thoracic inlet and ends where the esophagus penetrates the diaphragm. For surgical reasons, it is divided into two segments: a mid-thoracic segment, comprising supra-aortic and infra-aortic

esophagus. In the infra-aortic portion, the thoracic duct lies posteriorly, with the descending aorta and pleura on its left. On the right side are the pleura and the azygos vein, the latter being partly covered by the esophagus.

INTRODUCTION

Many factors make surgery of the esophagus technically difficult. Some of these are related to anatomic peculiarities. Others have to do with the ordinary problems of intrathoracic surgery, such as control of the open thorax and the maintenance of lung expansion sufficient to ensure adequate oxygenation of the blood. Because of great advances in the field of anesthesiology, the thorax may now be opened with as little risk as the abdomen. However, it was as recently as 1938 that Phemister and Adams were the first to perform a successful one-stage resection of the esophagus and the cardiac portion of the stomach.

APPLIED ANATOMY AND PHYSIOLOGY

The esophagus is a muscular canal which extends from the pharynx to the stomach. Its wall is composed of three layers: an inner mucous membrane, a submucous layer, and an outer muscular layer. Unlike other parts of the gastrointestinal canal, the esophagus has no serosal covering, and this fact has been mainly responsible for the failure of early attempts at resection and esophageal anastomosis. The mucous membrane is of the squamous cell type except for the most distal portion where the cells become columnar in character.

The circular and longitudinal muscle layers of the cervical and upper thoracic portions are composed entirely of voluntary muscle fibers. Below this level there is an increasing proportion of smooth muscle with a corresponding decrease of striated muscle, and, in the lower third, the musculature is entirely involuntary in type.

The main function of the esophagus is to convey fluid and food from the pharynx to the stomach. Food is propelled down the esophagus by peristaltic waves, but fluids descend mainly by gravity. Before food or fluid can enter the stomach, the very terminal portion of the esophagus must relax. Whether a true sphincteric mechanism exists here or not is still controversial. This area is designated the *cardiac sphincter*. The term *cardia* was originally introduced by Galen, who realized that disease in this area could simulate heart disease very closely. The mechanism that operates the sphincter is obscure, but it is dependent on the nerve supply of the esophagus which is derived from the vagi and the sympathetic trunks.

Normally, the esophageal lumen is narrowed at three points: (1) at the level of the cricoid cartilage, (2) where it is crossed by the left bronchus, and (3) where it pierces the diaphragm.

The esophagus is divided into cervical, thoracic, and abdominal portions. The cervical portion begins at the lower border of the cricoid cartilage, opposite the 6th cervical vertebra. Anteriorly, lie the trachea and the thyroid gland, while posteriorly are the vertebral column and the longus colli muscles. The common carotid arteries and part of the lateral thyroid lobes lie on either side of it. Between it and the trachea, the right and left recurrent nerves ascend. The thoracic duct lies to its left side.

portions, and a lower thoracic segment from the root of the lungs to the diaphragm. After entering the thorax, the esophagus rests upon the vertebral column, the longus colli muscles, the right intercostal arteries, the thoracic duct, and the hemiazygos and accessory hemiazygos veins. In front are the trachea, the left main bronchus, pericardium, and diaphragm. On the left side, in the supra-aortic part, lie the left subclavian artery, thoracic duct, and the left pleura, with the left recurrent laryngeal nerve between the trachea and the

Fig 273 —Segmental arterial blood supply of the esophagus

The thoracic portion begins at the thoracic inlet and ends where the esophagus penetrates the diaphragm. For surgical reasons, it is divided into two segments: a mid-thoracic segment, comprising supra-aortic and infra-aortic

esophagus. In the infra-aortic portion, the thoracic duct lies posteriorly, with the descending aorta and pleura on its left. On the right side are the pleura and the azygos vein, the latter being partly covered by the esophagus.

The vagus nerves descend in contact with the esophagus below the roots of the lungs, the right lying behind and the left in front.

The relationship of the thoracic duct to the esophagus is of great importance since this structure may be easily damaged during esophageal manipulation. In the infra-aortic segment, the thoracic duct lies posterior to and on the right of the esophagus. As it ascends it passes slightly to the left, lying closer to the esophagus. In the supra-aortic segment, the duct continues forward and, about midway in the superior mediastinum, ascends anteriorly and to the left until it enters the neck and terminates in the left subclavian vein.

The abdominal portion of the esophagus lies in the esophageal groove on the posterior surface of the left lobe of the liver. It is covered by peritoneum in front and on its left side.

Blood Supply.—The blood supply of the esophagus, which is much richer than was previously supposed, is segmental in distribution. The vessels, for the most part, run in a longitudinal direction. From above downward, the most important individual arteries are the following:

- 1 Inferior thyroid, supplying the cervical and supra-aortic segments
- 2 Branches from the inferior surface of the aortic arch
- 3 Branches of the bronchial arteries
- 4 Branches of the thoracic portion of the descending aorta
- 5 Inferior phrenic artery
- 6 Left gastric artery
- 7 Superior suprarenal arteries

The most critical level for resection is in the upper thoracic portion in the region of the tracheal bifurcation and arch of the aorta where the main blood supply is from the bronchial arteries and where the other collateral channels are minimal. Here, resection with anastomosis is precarious if the bronchial arteries are sacrificed, and therefore it should be performed at a higher level, where descending branches from the inferior thyroid arteries will assure blood supply adequate to prevent necrosis at the suture line.

The veins are arranged in two main groups. The external or periesophageal group follows

the course of their associated arteries. The internal group forms 10-15 parallel trunks which run longitudinally and are evenly distributed throughout the submucosa. The venous drainage of the upper esophagus is into the inferior thyroid and other systemic veins at this level, that of the lower two-thirds of the thoracic esophagus is into the azygos and hemazygos veins, while that of the abdominal portion is downward into the left gastric (coronary) vein which belongs to the portal system. Free communication between the systemic and portal venous systems is thus established. In portal hypertension there is a rerouting of blood upward through the longitudinal submucous venous plexus into the systemic system. As a result, the submucous veins become abnormally distended and dilated to form *esophageal varices*, often the source of massive gastrointestinal hemorrhage.

Lymphatics.—The esophagus has a rich network of intramural lymphatic vessels arranged in two main groups which drain the mucosa and submucosa and the muscular wall, respectively, with free anastomosis between them. The intramural lymphatics drain to the external surface and from there into three main groups of lymph nodes.

1 *Cervical portion.* Anterior superior mediastinal, the lower deep jugular, and the ipsilateral scalene lymph nodes.

2 *Upper thoracic portion.* Anterior mediastinal and retrotracheal nodes.

3 *Lower esophagus.* Nodes of the celiac ganglion and those along the lesser curvature of the stomach, particularly those along the left gastric artery.

The intramural lymphatics and the collecting vessels may ascend or descend to empty into distant nodes or may drain directly into adjacent nodes.

In esophageal cancer spread may occur directly into the closest lymph node or to those situated at a considerable distance above or below the lesion. Furthermore, the intramural lymphatic vessels may spread neoplastic cells longitudinally, 8-10 cm. above or below the visible and palpable limits of the primary cancer.

Nerve Supply.—The upper portion of the esophagus is supplied with motor fibers by the

recurrent laryngeal nerves which lie adjacent to it. Below this level, the vagal trunks are motor to the remaining musculature by way of the esophageal plexus, which also derives fibers from the thoracic sympathetic and splanchnic nerves. The sympathetic and parasympathetic fibers form a myenteric and submucous plexus within the wall. From experimental studies it has been shown that there is reciprocal innervation between the lower part of the thoracic esophagus and the terminal abdominal portion. The vagi are responsible for increased tone and motility of the

e.g., acute retropharyngeal abscess; and in the larynx, e.g., acute laryngitis, may make swallowing almost impossible. Neoplastic lesions of the pharynx and extrinsic larynx may exhibit dysphagia as the first symptom.

Neurologic disorders affecting the musculature of the pharynx constitute another group of causes of dysphagia. Among such disorders are included bulbar palsy, myasthenia gravis, postdiphtheritic paralysis, and functional disturbances as found in hysterical patients. In infants the mechanical defects of harelip and cleft palate should also be remembered.

Fig. 274—Classification of lesions causing dysphagia

esophagus and for producing relaxation of the cardiac sphincter, while the sympathetic system has the opposite action.

SYMPTOMS OF ESOPHAGEAL DISEASE

Dysphagia may be defined as the difficulty in swallowing either fluids or solid food. There are many inflammatory and neoplastic lesions of the mouth, pharynx, larynx, and esophagus which are manifested by this symptom. The student should remember that acute pain resulting from inflammatory lesions in the mouth, e.g., acute parenchymatous glossitis, acute stomatitis, and quinsy; in the pharynx,

Esophageal lesions causing dysphagia may be classified as follows.

A. Congenital causes: atresias, tracheo-esophageal fistulas, cysts, anomalous vessels, and hiatus hernia.

B. Acquired causes:

- 1 Within the lumen: e.g., foreign bodies such as coins, tooth plates, etc.
- 2 Within the wall
 - a Traumatic, e.g., structures caused by swallowing corrosives
 - b Inflammatory, e.g., peptic ulcer or esophagitis at cardiac end
 - c Neoplastic, e.g., carcinoma
 - d Idiopathic or neurogenic, e.g., cardiospasm

- 3 Outside the wall
 - a Esophageal pouches of pulsion or traction types which fill with food and compress the lumen from without.
 - b Enlarged mediastinal glands of inflammatory or neoplastic origin
 - c Neoplasms infiltrating or compressing from without
 - d Aneurysms of the aorta
 - e Hiatus hernia

Pain may be present only on swallowing or the patient may complain of attacks of substernal distress, either sharp and severe or dull and aching in character.

Regurgitation of undigested food occurs fairly commonly, particularly in the presence of a pharyngoesophageal diverticulum or of cardiospasm.

Hemorrhage into the esophageal lumen may produce blood-tinged vomitus and is caused by ulceration, foreign body erosion, or bleeding varices (see Chapter 19).

EMBRYOLOGY AND CONGENITAL ANOMALIES

(See Chapter 30)

FOREIGN BODIES

Infants and children are most prone to the hazard of foreign bodies in the esophagus, but such are not infrequently seen in adults.

The majority of such accidents is the result of carelessness. In adults, this complication results from the failure to detect bones or other hard substances in swallowed foods, from poorly masticated meat, or from the loss of poorly fitting or damaged dentures. Psychotic patients may intentionally swallow foreign bodies. In children, coins, nails, tacks, screws, safety pins, buttons, meat, and fish bones are the most common foreign bodies concerned.

Such an object may lodge almost anywhere in the esophagus but is usually arrested at the level of the cricoid cartilage. If it passes this point it will usually proceed to the cardiac sphincter or into the stomach. In some cases it may lodge at the other sites of natural narrowing, i.e., at the level of the aortic arch and of the left main-stem bronchus.

The presence of esophageal disease may block the passage of substances which normally descend without difficulty.

Symptoms.—The symptoms vary from vague discomfort or a sticking sensation to severe pain and dysphagia. In an adult it is generally possible to obtain a history of a swallowed foreign body, but in a child this information may be completely lacking. Pain is usually localized, by the patient, on the body surface corresponding to the level of lodgment in the neck or chest. Dysphagia may

Fig. 275.—Foreign body (coin) impacted at level of cricoid.

result, and, if severe, is accompanied by an accumulation of saliva in the hypopharynx which finally overflows into the trachea, producing choking and coughing. Eventually, if the foreign body remains in situ, perforation may occur, producing acute mediastinitis, mediastinal abscess, or an erosion of a major blood vessel with fatal hemorrhage. In other cases a fistula may be produced between the trachea or bronchus and the esophagus and, in long-standing cases, stricture formation follows.

Diagnosis.—This is made from the history and symptoms. Examination of the hypopharynx may, on rare occasions, reveal the presence of the foreign body. Careful x-ray studies are useful, especially when the foreign bodies are radiopaque, or, if radiolucent, a barium swallow will outline the object or reveal the presence of obstruction. If perforation is suspected, Lipiodol instead of barium should be used.

Treatment.—The primary treatment is endoscopic examination and extraction. Operative intervention is necessary when endoscopic removal has failed and when complications such as perforation with an associated mediastinitis or abscess formation, stricture, or hemorrhage has occurred.

STRICTURE

Benign strictures may occur from a variety of causes. The majority result from the accidental swallowing of caustic chemicals, which produce acute inflammation and secondary scarring. The ingestion of such material occurs mainly in children and is commonly caustic soda or lye (see Chapter 30). The patient may complain of substernal burning, epigastric pain, excessive salivation, and vomiting but is usually able to swallow normally for a few days after the accident. However, after 1-2 weeks there is slight difficulty in swallowing solids, which becomes progressively more severe until the patient is finally unable to take fluids. Prolonged dysphagia results in progressive weight loss, weakness, anemia, vitamin deficiency, and general malnutrition. Very severe burns may produce a secondary mediastinitis with its accompanying symptoms.

Benign strictures may also occur following the impaction of a foreign body, gunshot wound of the esophagus, benign tumors, peptic

esophagitis, or following operations for tracheo-esophageal fistula or esophageal diverticulum.

Treatment.—A person who is suspected of having swallowed a caustic agent should be hospitalized as soon as possible and an attempt made to establish the nature of the material swallowed. Immediate neutralizing substances should be used, such as vinegar after alkali, bicarbonate of soda after acids, and milk or egg white after phenol. Examination of the oral cavity, the pharynx, and larynx may reveal the presence of a burn. In such cases laryngeal edema may ensue and a tracheostomy be required if there is the slightest suggestion of resulting respiratory difficulty.

If the patient is able to take nourishment by mouth, a soft liquid diet is given. If, however, swallowing becomes impossible, a gastrostomy must be performed for feeding purposes. Esophageal dilations, using olive-tipped dilators or mercury-filled bougies specifically designed for this purpose, are commenced as soon as possible in order to re-establish and maintain adequate passage.

A chronic or well-established stricture requires careful roentgenographic and esophagoscopy studies to determine its exact site and extent. In these cases, following preliminary gastrostomy, dilations are performed, using flexible-tipped dilators or olive-tipped bougies passed over a previously swallowed thread.

In other cases of well-established tight strictures, heavy silk thread is swallowed and brought out through the gastrostomy. One can thus carry out rapid and frequent dilations with bougies of increasing size either in a retrograde or peroral manner, using the silk thread as a guide.

Strictures that are caused by benign tumors, foreign bodies, and peptic esophagitis are discussed more fully in the section dealing with these conditions. Localized strictures, such as those following diverticulectomy, gunshot wounds, or stabbing, may be amenable to resection and end-to-end anastomosis. In more extensive strictures, more radical operative procedures may be necessary, such as excision with esophagogastrostomy or esophagojejunostomy. In selected cases an isolated segment of upper jejunum may be anastomosed between the resected esophagus and the stomach.

In more extensive strictures, more radical operative procedures may be necessary, such as excision with esophagogastrostomy or esophagojejunostomy. In selected cases an isolated segment of upper jejunum may be anastomosed between the resected esophagus and the stomach.

ESOPHAGEAL DIVERTICULA

Diverticula are classified according to their anatomic position and their method of origin. The following types of diverticula are recognized:

- 1 Pharyngoesophageal (pulsion type)
- 2 Epibronchial (traction type)
- 3 Epiphrenic (pulsion type) (see Plate 15)

Pharyngoesophageal Diverticulum

This is a pulsion diverticulum that occurs characteristically on the posterior wall at the pharyngoesophageal junction. At this point, the inferior constrictor or cricopharyngeus muscle is divided into two muscle bundles, i.e., an upper oblique and a lower transverse. There is usually a slight gap, a weak area, frequently called the pharyngeal dimple, between these two sets of muscle fibers. During the act of swallowing, food is projected from the back

Fig 276—Stages of esophageal diverticula

of the tongue and impinges on this weak part of the pharyngeal wall. Furthermore, a peristaltic wave, beginning in the nasopharynx and passing downward to the pharyngoesophageal junction, is initiated by the pharyngeal constrictor muscles. The upper oblique fibers of the inferior constrictor are propulsive, while the lower transverse fibers are said to be sphincteric in action. If the coordination involving the relaxation of the lower transverse fibers fails to occur while the propulsive wave is active during this initial peristaltic wave, undue pressure will be exerted by the bolus of food at the pharyngeal dimple. A small bulge develops at this point, and the mucous membrane is eventually herniated as a pouch between the two parts of the inferior con-

strictor muscle. The ultimate development of the diverticulum is merely a matter of repetition of this mechanism. A true sac, consisting of mucosa and submucosa, is formed and eventually is of sufficient size to retain food and saliva and give rise to symptoms.

Symptoms.—The symptoms depend upon the stage of sac development and are directly referable to the act of swallowing. They may be absent or range from minimal discomfort to progressively increasing dysphagia and regurgitation. Regurgitation of previously swallowed materials into the pharynx is probably the most frequent complaint and occurs in the majority of patients with well-established pharyngoesophageal diverticula. Another frequent complaint is the occurrence of gurgling noises during deglutition of liquids. This symptom may become so noticeable as to embarrass the patient. At other times, patients complain of obstruction, which is usually described as a sticking or a delay of food passage in the throat, lasting only a few minutes and relieved by taking fluid or by pressure against the side of the neck. In the very large diverticulum, the sac extends into the superior mediastinum and distorts the esophageal wall so that the normal esophageal opening is now directly into the sac. Here, complete esophageal obstruction occurs associated with progressive weakness, malnutrition, and weight loss.

Diagnosis.—In addition to a suggestive history, x-rays with barium swallow will demonstrate a sac which communicates with the esophagus. Esophagoscopy, which may be employed for confirmatory purposes, carries with it the danger of perforation through the diverticulum.

Treatment.—When symptoms are sufficiently severe, surgical resection of the sac must be performed. The incision employed is usually oblique, following the anterior border of the left sternomastoid muscle. A collar incision may also be used. Formerly the two-stage operation was widely practiced to minimize the development of acute mediastinitis. In the first stage the diverticulum was mobilized and the fundus suspended to the adjacent tissues at a point above its origin. Ten to 14 days later, after fibrosis had sealed off this area, the

sac was excised and the defect in the esophageal wall closed.

Today chemotherapy diminishes the risk of mediastinal infection, and the one-stage resection is practiced.

Complications.—Serious complications may occur following such operations.

1. Injury to the recurrent laryngeal nerve may occur. This nerve must be carefully identified and protected during the operation.

2. Injury to the thoracic duct is possible. This complication is rare. Severance, if unrecognized, will result in a chylous fistula with its serious sequelae.

3. The occurrence of a fistula at the site of resection is usually temporary and closes spontaneously with conservative management. However, large or persistent fistulas may require secondary surgery for closure. Rarely, the fistula is caused by an unrecognized obstructing esophageal web below the site of the diverticulum. After excision of the pouch, routine exploration of the esophageal lumen is necessary. A web, if present, should be excised.

4. Stricture formation may result from inadvertent inclusion of a portion of the esophageal wall with the sac. Strictures may also occur following healing of a fistula and may require subsequent dilatations or secondary operation.

5. Local infection with mediastinitis and abscess formation is sometimes associated with large diverticula with peridiverticulitis. In such cases it may be preferable to employ the two-stage method of removing the diverticulum.

Epibronchial Diverticulum

This is a traction diverticulum and is commonest in the mid-portion of the esophagus at the level of the main bronchi. Inflammatory processes in adjacent lymph nodes produce adhesions to the esophagus which gradually contract. As a result, the wall of the esophagus is pulled out in tentlike fashion.

Since their walls contain all layers of the esophagus, the mucosa, submucosa, and muscularis, they are true diverticula. They rarely exceed 2 cm in diameter and have a broad neck and a contracting muscular wall which prevents retention of food.

These lesions are common, occurring in approximately 35% of all autopsies. The majority are asymptomatic and without clinical significance. Occasionally patients may complain of mild substernal burning and pain.

Traction diverticula are easily demonstrated by barium swallow.

Treatment.—Treatment is unnecessary in most cases, but if severe symptoms are present, excision employing a transthoracic approach is indicated.

Fig. 277.—Traction diverticulum at typical site, bifurcation of trachea.

Epiphrenic Diverticulum

These pulsion type diverticula occur most frequently at a point in the esophagus several inches above the diaphragm. Corresponding to the pharyngoesophageal diverticula, those which develop in this region consist of a pouch of

mucosa appearing between the fibers of an attenuated muscular layer.

Etiology.—The etiology of epiphrenic diverticula is obscure. Some believe they are congenital in origin, while others feel that they are produced as a result of distal esophageal obstruction with herniation of the mucosa through a weakened muscular area.

Symptoms.—In the majority of patients, the symptoms at first are vague and indefinite. In some, pain and burning referred to the substernal area and the lower back may be present. Varying degrees of dysphagia may result from the distended diverticulum and the pressure and distortion it produces. In the rare complicated case, complete mechanical obstruction may result with subsequent weight loss, malnutrition, and weakness. Diagnosis is established during barium swallow.

Fig 278—Pulsion diverticulum in lower esophagus

Treatment.—Mild symptoms can be relieved by conservative therapy, prescribing soft bland foods, a full glass of water after each meal to wash out the sac, and antispasmodics. Severe persistent symptoms necessitate resection of the sac with repair of the defect in the esophageal wall. A transthoracic approach from the side to which the diverticulum presents is employed.

RUPTURE OF THE ESOPHAGUS

Rupture of the esophagus may occur as a result of trauma, inflammation, or eroding neoplasm. It may also occur spontaneously in a perfectly normal esophagus.

Traumatic Perforation

Most traumatic perforations result from endoscopic procedures or follow the impaction of foreign bodies. Osteoarthritic spurs in the cervical vertebrae may bruise and perforate the esophageal wall during endoscopy. Perforation may also follow procedures such as biopsy or instrumental dilatation. The esophagus, being a deeply seated organ in the cervical and thoracic regions, is rarely involved by external violence.

Signs and Symptoms.—Those resulting from rupture of the esophagus are not always immediate and depend on the size and location of the perforation. Perforation should always

Fig 279—Traumatic perforation, lower esophagus, 3 hours following esophagoscopy. Note free air beneath diaphragm.

be suspected when pain or discomfort follows endoscopy or the ingestion of a foreign body or caustic material.

In perforation of the cervical esophagus, local tenderness beneath the sternomastoid muscle and crepitation of the soft tissues of the neck are early signs. Dysphagia, hoarseness, pain, and tracheal stridor usually appear 3-5 days later. Usually present are a rising temperature, increased pulse and respiratory rates, a sore throat, and leukocytosis. X-rays of the neck and superior mediastinum may reveal some widening of the prevertebral soft tissue shadow or a retropharyngeal gas pocket with fluid

level. Extension downward to the superior mediastinum will result in a superior mediastinal abscess clearly visualized on x-ray. The fascial planes of the neck are responsible for the route of spread for infection produced by a perforation (see Chapter 12).

Perforations of the thoracic esophagus are generally associated with mediastinitis, pleuritis, pleural effusion, or peritonitis. Perforations into the pleural cavity are followed rapidly by accumulation of fluid and air in the pleural space. A tension pneumothorax may develop accompanied by severe dyspnea and cyanosis. Physical findings may be minimal, and a chest x-ray may reveal mediastinal emphysema, mediastinitis, free air in the pleural space or beneath the diaphragm, or a frank pleuritis and hydropneumothorax.

Rupture of the lower esophagus is usually associated with severe substernal and epigastric pain, and the signs and symptoms of peritonitis are present. Perforations immediately above or below the hiatus produce this picture.

Treatment.—Successful treatment of this condition depends largely upon early diagnosis and active operative treatment. Antibiotic therapy combined with suitable repair and drainage procedures is mandatory. Tracheostomy may be required in some cases.

Conservative management of perforations involving the cervical esophagus is generally successful, especially in patients having small perforations involving the mucous membrane only. Intensive antibiotic therapy combined with bed rest, nasogastric suction, and no oral feedings will control the spread of infection and result in complete recovery in a large percentage of cases. In more complete perforations where the infection has had a chance to become well established, an acute retropharyngeal abscess may result in extension downward into the superior mediastinum. Such cases urgently require cervical mediastinotomy for drainage and decompression of the tense abscess.

If the abscess is confined to the neck it may be approached by an incision behind the sternomastoid muscle. An emergency tracheostomy may be necessary because of acute respiratory difficulty associated with edema and swelling about the larynx. The usual supportive measures are also prescribed.

Patients with lacerations of the thoracic esophagus rarely survive with conservative management, particularly where the perforation has extended into the pleural cavity. Once the pleural space is contaminated, immediate open operation is the only means of preventing almost certain death. A thoracotomy, with repair of the torn esophagus and suitable drainage of the pleural cavity, must be performed.

Spontaneous Rupture

Spontaneous rupture of the esophagus is an extremely rare condition which occurs four times more frequently in males than in females. In certain cases the cause is some pre-existing weakness of the esophageal wall, which gives way when intraesophageal pressure is suddenly increased. This usually occurs in the lower third on the left posterolateral wall, and is followed by rupture into the left pleural space. It may, however, occur through the left anterolateral wall. The mortality rate which in the past was 100% has been reduced in recent years to approximately 30% by early diagnosis and prompt surgical intervention.

Diagnosis.—The patient is commonly a previously healthy male, robust, a heavy eater, and possibly an alcoholic, who complains of excruciating pain immediately following a bout of vomiting, which may have been either spontaneous or induced. The pain is epigastric, radiating to the left side of the chest and to the back. Dyspnea, cyanosis, and shock develop rapidly. Hematemesis is rarely copious. Vomiting generally ceases after the onset of pain and is followed by intense thirst. Some patients present a history of previous ulcer, esophagitis, or esophageal stricture. Physical examination reveals severe shock and a unilateral (usually left) or bilateral hydropneumothorax. Subcutaneous emphysema is present at the base of the neck in 60% of cases. Perforated peptic ulcer, acute pancreatitis, mesenteric thrombosis, dissecting aneurysm of the aorta, coronary thrombosis, pulmonary embolism, and spontaneous pneumothorax must be excluded.

The presence of hydropneumothorax associated with shock and vomiting is almost path-

thognomonic At an early stage, x-rays reveal mediastinal emphysema, which ascends rapidly into the cervical region. They may also demonstrate fluid levels in the mediastinum and in the pneumothorax. Extravasation of radiopaque oil introduced into the esophagus further confirms the rupture. Aspiration of the pleural cavity yields fluid characteristic of gastric or esophageal contents.

Fig 280—Hydropneumothorax caused by spontaneous perforation of lower esophagus

Treatment.—Control of shock, decompression, and drainage of the tension pneumothorax and replacement of oral feedings by parenteral fluids are immediate requirements. Chemotherapy is instituted. Thoracotomy is performed with closure of the esophageal tear. The mediastinum and pleura are cleansed and drained. A nasal catheter is introduced to prevent postoperative distention of the stomach.

ACHALASIA

(Synonyms: Idiopathic Dilatation, Cardiospasm)

Early theories postulated that in this condition proximal esophageal dilatation was produced by failure of the cardiac sphincter to open reflexly during the act of swallowing. The term *achalasia*, meaning lack of relaxation, was then adopted. Absence of hypertrophied muscle fibers in the narrowed portion of the esophagus led others to assume that there had occurred progressive degeneration of Auerbach's

plexus in this region. Whatever the cause, cardiospasm accounts for approximately 20% of all patients complaining of dysphagia. It is commoner in the female than in the male. Although cardiospasm has been recorded in infancy, most cases appearing for treatment are in the third or fourth decade of life. In some cases there seems to be a definite psychogenic factor.

Pathologic Features.—The narrowed segment is a thin, pale area, 3-6 cm. in length just proximal to the stomach; the muscular coats are to some degree replaced by fibrous tissue, and degeneration of myenteric ganglia is evident. Proximal to this the esophageal musculature may be very thick and hypertrophied, and in long-standing cases the wall stretches and becomes tortuous.

The radiologic deformity is at first a funnel-shaped dilatation which, in the later stages, becomes flask-shaped and ultimately assumes a sigmoid form.

Symptoms.—Patients with cardiospasm can feel the esophagus contract when they are excited. The first swallows of food pass easily, but there soon follows a sensation of fullness behind the lower portion of the sternum. Symptoms of dysphagia are aggravated by rapid eating, roughage, and hot or cold fluids. As the disease progresses, regurgitation may result in aspiration pneumonia or pulmonary abscess.

Diagnosis.—X-ray examination and esophagoscopy are confirmatory. The latter is particularly helpful in distinguishing between cardiospasm and esophageal carcinoma. In advanced cases, aspiration by catheter will recover putrefying food products.

Treatment.—Treatment is divided into medical and surgical phases. Medically, a bland diet, antispasmodics, and psychotherapy are worthy of trial. If the disease progresses, dilatation by means of a mercury-loaded bougie or a hydrostatic bag will bring relief to some patients. If repeated dilations are necessary, the patient can often be taught to pass it on himself. There is a definite hazard of accidental perforation when the esophagus is edematous, friable, and tortuous.

A special balloon catheter has been designed which is introduced through the cardiac sphincter.

Plate 15.—Types of Esophageal Diverticula.

Fig 281 —X-ray appearance in advanced cardiospasm, showing markedly dilated esophagus. Inset shows area of spasm at cardioesophageal junction

Fig 282 —Cardiospasm dilated under x-ray control, using a pneumostatic balloon

ter after a suitable dilatation. The balloon is positioned and is then inflated with air or water under pressure and the narrowed segment is stretched. This method appears to be dependent on the uncontrolled rupture of the muscular coat in the spastic area. Advocates of pneumostatic or hydrostatic dilatations report good results, but the risk of rupture with its very serious sequelae is a reason in favor of operative treatment in most instances.

Some form of surgical treatment must be considered for those patients who fail to obtain relief from dilatation. Many operative procedures have been devised and, in particular, several types of cardioplasty have been tried. They have, however, the distinct disadvantage of destroying the competence of the cardiac sphincter, and reflux esophagitis is a frequent complication.

The Heller operation (1913) appears to give the most consistent and best results in the surgical management of advanced cardiospasm. It is similar in concept to the Fredet-Rammstedt operation for congenital hypertrophic pyloric stenosis. Originally, Heller made two longitudinal incisions, one anterior and one posterior, through the muscular layers of the area of cardiospasm (cardiomyotomy), allowing the submucosa and mucosa to bulge outward. In current practice, only an anterior incision is utilized, and when carefully performed, incompetence of the cardia, allowing esophageal reflux, is absent or very minimal. The operation may be done through the abdomen or thorax, the latter approach being preferable.

REFLUX ESOPHAGITIS

Chronic intermittent regurgitation of digestive juices into the lower esophagus produces a chemical inflammation, designated reflux or peptic esophagitis. In most instances this entity appears to be the result of diffuse inflammatory erosion, ulceration, and scarring produced by prolonged reflux of gastric juice in the presence of an incompetent cardioesophageal sphincter and frequently associated with hiatus hernia. Reflux of alkaline juices into the esophagus, after surgical procedures such as esophagojejunostomy, can also cause an identical type of esophagitis. This entity

Fig 283—Benign esophageal stricture caused by prolonged nasogastric intubation

is an important cause of chronic dyspepsia, so-called heartburn and dysphagia, and it seems likely that its incidence is much higher than has been previously suspected.

Etiology.—In general, the methods of production of reflux esophagitis and the various factors involved are understood. However, there is no agreement on the factor in the digestive juices specifically responsible. Abundant experimental evidence demonstrates the susceptibility of the esophageal mucosa to acid-peptic digestion. The following fact may be etiologic:

- 1 Incompetence of the cardioesophageal mechanism in the presence of sliding hernia or following operations involving the cardioesophageal junction
- 2 Gastric hypersecretion and peptic ulcer diathesis
- 3 Protracted vomiting, nasogastric intubation, and pyloric obstruction
- 4 Ectopic gastric mucosa occurring in association with a short esophagus
- 5 Individual susceptibility

Reflux esophagitis is most often associated with sliding hiatus hernia where the esophago-gastric junction is displaced and the normal mechanism preventing reflux is absent. Regurgitation of gastric contents may then occur, especially when accentuated by pyloric obstruction or spasm, increased intra-abdominal pressure associated with obesity, or merely the assumption of the reclining position. The association of peptic duodenal ulceration with reflux esophagitis is high (40%) and a true ulcer diathesis with its associated hyperchlorhydric state, nervous tension, and individual susceptibility is generally agreed to be present in most cases. Frequently, the symptoms of esophagitis may be identical to those of duodenal ulcer.

Pathology.—The typical lesion occurs in the lower third of the esophagus, and four stages in its natural history are described, i.e., esophagitis, esophagitis with acute ulceration, esophagitis with chronic ulceration, and healed fibrous stenosis. At first the esophagus retains its natural elasticity and the associated hernia can be reduced when the patient is upright. Chronic ulceration progresses and the inflammatory reaction results in chronic submucous fibrosis around the lower third of the esophagus. Later this fibrotic tissue contracts and produces not only stenosis but also shortening of the esophagus, which draws the stomach up through the hiatus and fixes it in this position. The acid gastric juice continues to act unopposed on the esophageal mucosa, and the condition is continuously aggravated. The histologic appearance usually includes superficial ulceration with granulation tissue, extensive submucous fibrosis with edema and thickening of the wall, and infiltration of the musculature with chronic inflammatory cells.

Symptoms.—The clinical features are dominated by a common form of indigestion consisting mainly of heartburn, gastric flatulence, and postural regurgitation. Three varieties of pain may be noted: (1) high epigastric discomfort associated with high acid secretion, (2) burning retrosternal pain from acid irritation of the inflamed esophagus, and (3) a deep, boring pain made worse by flexing the spine. In adults, the commonest symptom is dysphagia followed by dyspepsia and less commonly by bleeding. Loss of weight is pro-

portional to the degree of obstruction and starvation. Pain may be precipitated by lying down or stooping forward, especially after eating, and relief is obtained by drinking milk or alkaline beverages. With advanced esophageal inflammation, intermittent dysphagia and bouts of partial or complete obstruction occur.

Diagnosis.—This is established by the history and by the radiologic and esophagoscopic examinations. The radiologic demonstration of esophagitis may be difficult. Advanced cases may show stenosis and stricture formation in the lower esophagus with proximal dilatation. In early cases, close inspection may reveal fuzziness of the mucosal pattern with spasm as evidenced by lack of distensibility of the

FIG 284.—Reflux esophagitis with stricture. Arrows indicate peptic esophageal ulcer, sliding hiatus hernia, and diaphragm.

esophagus and sometimes small areas of ulceration. Frequently it is impossible to locate the cardioesophageal junction since the stomach may be pulled through the hiatus like a sleeve, and there is no clear demarcation between the esophagus and stomach. This knowledge is important for the surgeon. In the cases associated with hiatus hernia, a reflux of the barium into the lower esophagus may be easily seen in the early cases. Sometimes a hiatus hernia may be difficult to demonstrate, and examination in the Trendelenburg position should always be attempted for this reason.

Esophagosopic examination should be carried out in all suspected cases of esophagitis for the following reasons: (1) the degree of esophagitis, ulceration, and stenosis can be evaluated, (2) carcinoma may be ruled out by biopsy, (3) the level of the cardioesophageal junction can be accurately established and verified by the application of a silver clip which may be later demonstrated by x-ray to be above the diaphragm, and (4) information can be gained concerning the amount of fixation of the lower esophagus to the mediastinal structures.

The *endoscopic examination* shows a characteristic hyperemia and edema of the mucosa in the lower third of the esophagus which frequently bleeds easily on contact. Ulcers may be noted and the cardia is lax and patulous, the instrument passing easily into the stomach without deviation.

Treatment.—The treatment of this condition may be medical or surgical. All early cases of esophagitis and those with symptoms of moderate degree should be given a trial of *medical therapy* consisting essentially of an ulcer regime including an antacid, an antispasmodic, a bland diet, and sedatives. Conservative treatment may considerably relieve symptoms. Patients are advised to remain erect after meals, avoid stooping and bending, and to sleep with the head of the bed elevated. *Weight reduction and the removal of constricting belts and tight clothing* may be necessary to decrease intra-abdominal pressure. Many patients will obtain symptomatic relief, but those who fail to respond and those with destruction of the mucosa and progressive fibrotic stenosis may require surgical treatment.

The *surgical treatment* has as its first objective, prevention of reflux by restoring the normal cardioesophageal relationship, i.e., by correcting an existing hiatus hernia. The technique of Allison has been universally favored in this respect. Second, rapid drainage of the esophagus is secured by relieving any obstruction distal to the esophagus, such as pylorospasm. This has resulted in the use of the Finney pyloroplasty for the relief of symptoms associated with this condition, and this appears of benefit in the early phase of the disease. A third objective is the reduction of gastric acidity. For this Wangenstein has proposed subtotal gastrectomy to eliminate the acid-peptone secretions. He claims great success for this operation even in patients with stricture formation.

Obstruction of the esophagus itself must be relieved, and, in addition, other associated gastrointestinal disease must be eliminated. When esophagitis has progressed to a fixed, shortened esophagus with fibrous stricture, dilatation and bouginage may be performed. Extreme stenosis with dysphagia and weight loss require radical surgery. Excision of the stenotic portion with radical proximal gastrectomy is performed. Continuity is re-established by rolling the distal stomach segment into a tube and anastomosing it high to the esophagus. The operation is completed by pyloroplasty, which allows rapid emptying of the stomach remnant. Other operations that utilize isoperistaltic Roux loops of small bowel to by-pass the stomach or to serve as valvular units between the stomach and esophagus are also advocated. These, however, appear to carry a much higher incidence of digestive disturbances, especially those which by-pass the stomach altogether.

TUMORS

Benign tumors are uncommon at any age, whereas malignant neoplasms (carcinoma) are relatively common in adults.

Benign Tumors

Most of this group arise from the non-epithelial tissues of the esophageal wall. Of these, the leiomyoma occurs most commonly. The average age incidence is 40 years, in con-

trast to that for carcinoma which is 60 years. Males are affected twice as often as females.

Symptoms.—Contrary to general belief, these lesions frequently give rise to symptoms, the commonest being pain and dysphagia of varying severity. Bleeding is not a characteristic feature because of the extramucosal origin of the tumor. However, ulceration of the overlying mucosa with hemorrhage may occur.

They are most commonly found in the lowest third and least commonly in the upper third of the esophagus. The tumor is ovoid in shape and averages 6 by 4 cm in size. Malignant changes producing a leiomyosarcoma rarely occur.

Diagnosis.—The diagnosis suggested by the history is established on barium swallow examination and esophagoscopy. A barium-filled esophagus will characteristically show a smooth-filling defect with sharp outlines between the upper and lower limits of the tumor, with a normal esophagus above and below it. An esophagoscopy will generally reveal a firm extramucosal tumor encroaching on the lumen, with an intact, healthy overlying mucosa, although, rarely, ulceration may be present. A biopsy, if sufficiently deep, will establish the histologic nature of the lesion.

Treatment.—The majority of these tumors are removed by simple enucleation through a thoracotomy. A tumor in the lower third is best approached through the left chest, while those in the middle and upper thirds are more easily removed from the right side. Rarely, a tumor may be so large and adherent to the wall that simple enucleation is not feasible and esophageal resection is necessary.

Other less frequently encountered benign tumors include fibromas, lipomas, myxomas, and neurofibromas.

Bronchogenic or esophageal cysts are congenital lesions arising from the primitive foregut. Bronchogenic cysts are generally found near the upper end of the thoracic esophagus, are lined by ciliated columnar epithelium, and usually contain cartilage in the wall. A cyst of esophageal origin situated in the mid-thoracic region may also contain ciliated epithelium, but when located near the diaphragm the lining is usually squamous in type. Cartilage is not present in the wall. The diagnosis and treatment are similar to those for leiomyoma.

Carcinoma

Carcinoma of the esophagus, on this continent, accounts for approximately 4% of all gastrointestinal malignant growths and 2% of all deaths from cancer. Its incidence is proportionately higher in males than females in the ratio of 5:1, reaching its peak in the 6th and 7th decades of life. In Sweden and Finland, where the Plummer-Vinson syndrome occurs commonly in the female, the incidence in the two sexes is practically equal. In China 50% of carcinomas involving the alimentary tract arise in the esophagus.

The location of the primary growth is as follows: upper third (cervical) 20%, mid-third (supra-aortic, infra-aortic) 33%, and lower third (lower thoracic, abdominal) 45%.

Pathology.—Most esophageal cancers are epidermoid or undifferentiated in cell type and arise from the mucous membrane. Adenocarcinoma, when it occurs, is generally found at the lower end of the esophagus. It may represent an upward extension of a primary adenocarcinoma arising in the cardia or may originate in ectopic gastric mucosa or from mucous glands present in the esophageal wall. The gross appearance of the cancer varies from a bulky fungating tumor projecting into the lumen to a growth spreading superficially and infiltrating the mucosa without obstruction to the passage. Submucosal infiltration may occur through the rich intramural lymphatics for some distance beyond the apparent borders of the lesion. This is only recognized on histologic examination.

Direct extension to important structures within the neck, thorax, and abdomen is common. When the primary growth is situated in the upper third, the trachea, recurrent laryngeal nerves, and great vessels may be invaded. When the carcinoma originates in the middle and lower thirds, infiltration of the left bronchus, thoracic duct, aortic arch, descending aorta, pericardium, and diaphragm may be present. Perforation into the mediastinum or pleural cavity produces mediastinitis or a pyopneumothorax.

The routes of possible lymphatic spread have been previously described. Metastases to the lung, liver, brain, bones, and kidneys by way of the blood vessels may also occur.

Symptoms—Early symptoms are often indefinite and cause little suspicion or alarm. There may be a sensation of dryness, tickling in the throat, or a vague discomfort on swallowing. Substernal pressure or distress associated with a sensation of fullness is sometimes present. The most significant symptom is dysphagia, at first with solid and later with soft and liquid foods. In time, progressive weight loss, weakness, and malnutrition follow. Pain is not an early symptom; when present and persistent it generally indicates extension of the growth beyond the esophageal wall.

type are established by esophagoscopy with biopsy.

Treatment—The management depends on the general state of the patient, the site of the primary growth, and the extent of its spread.

Surgical excision offers the best chance of cure for the early cases of lower third and cervical growths, whereas for those cancers in the mid-thoracic portion, the results of surgical procedures have been disappointing, and the recent use of high-voltage rotational radiation therapy has been securing promising results.

Fig. 285 —Palliative procedures for esophageal obstruction due to malignant disease

Diagnosis—Diagnosis of an esophageal cancer in an early stage is only possible by employing a barium swallow and esophagoscopy in any patient who presents suspicious symptoms. Clinical examination provides little assistance and the earliest lesions can only be diagnosed by endoscopy. The extent of the tumor is best determined by x-ray examination, while the presence of cancer and its histologic

The primary objective of the radical surgical procedures is the complete removal of the growth, together with a length of normal adjacent esophagus above and below the neoplasm, and all the adjacent lymph nodes, with the re-establishment of the continuity of the digestive tract. Unfortunately, when first seen only 50-60% of patients are operable. The remainder present one or more features

which immediately establish the inoperability of the condition, such as metastases to the supraclavicular lymph nodes, paralysis of a vocal cord, Horner's syndrome, tracheo- or broncho-esophageal fistula, evidence of metastases to liver, lungs, bones or other organs, or endoscopic evidence of the fixation of the lesion to adjacent structures.

Because of earlier diagnosis, safer anesthesia, improved operative techniques, and general supportive measures, an increasing number of cases are being explored. Formerly, multiple-stage procedures were performed and included esophagostomy, gastrostomy, resection of the lesion, and, finally, the joining of the upper esophageal segment to the stomach by means of extrathoracic tubular skin grafts (Grey-Turner). In recent years the left thoracoabdominal approach has enabled successful anastomoses to be performed as high as the cervical portion of the esophagus. Continuity is re-established by esophagogastrostomy or esophagojejunostomy after mobilization of the stomach or Roux loop of jejunum. This approach and the associated anastomoses have been especially successful for growths of the lower third of the esophagus. A right transpleural approach is favored for growths of the upper and middle thirds, and similar types of anastomoses are utilized.

A substitute esophagus consisting of an isolated mobilized segment of jejunum with an intact blood supply may be passed through a tunnel in the loose tissue immediately behind the sternum and anastomosed to the esophagus proximally and to the stomach distally.

Recently, anastomosis with the jejunum has been made after passing the loop of intestine through a tunnel in the loose tissue lying just beneath the sternum.

Specialized techniques have been developed for resection of the growths involving the cervical esophagus. When spread to the larynx or cervical nodes is present, concomitant laryngectomy or radical neck dissection is required. The Trotter or Wookey procedure consists of excision of the cervical esophagus and reconstruction by means of a full-thickness skin graft taken from the lateral cervical region, rolled into a tube, and anastomosed between the severed ends of the esophagus.

Others have used a skin graft wrapped around a cone-shaped tantalum-mesh framework which generally can be removed through the mouth in 2-3 weeks, leaving behind a skin-lined tube to bridge the defect.

For the inoperable cases, palliative procedures to minimize the distressing pain, dysphagia, regurgitation, inanition, and associated complications must be considered.

For the purpose of feeding the patient, a Souttar's tube may be placed by endoscopy through the constricted lumen, or a plastic tube with a proximal shoulder may be forced directly through the growth area when thoracotomy proves it to be unresectable. The opening made in the normal esophagus above the growth for the insertion of the tube is sutured. In cases where direct examination indicates that the growth is inoperable, a bypass procedure can be carried out. This is usually accomplished by anastomosing a segment or loop of jejunum to the esophagus above the obstruction.

In other cases a gastrostomy is performed. This was formerly the routine treatment, but it is now known that it in no way prolongs life and alternate procedures are under trial. Associated with the above measures, high-voltage radiation therapy is given and affords symptomatic relief.

Results.—The prognosis in carcinoma of the esophagus is improving but remains poor.

In general, approximately 42-68% of the cases seen by the surgeon are suitable for surgery. Resection is possible in about 78% of these cases, that is, in 53% of all cases. If cases of carcinoma involving the cardiac end of the stomach are included, resection can be carried out in 70% of all cases encountered.

The immediate operative mortality rate is 14% for lesions below the aortic arch and 33% for those located above this level. The average operative mortality varies from 20-25%. Long-term survival statistics indicate that if one includes all types of carcinoma of the esophagus, there is an over-all 24% 3-year survival rate with a 10% 5-year survival rate.

Mustard (1956) reported the experience at the Toronto General Hospital (1937-1953) with 381 cases. For the entire group 8 cases,

or 3%, survived 5 years
had the best prognosis

86 untreated patients—2 survived 2 years
100 patients with palliative gastrostomy—6 survived 1 year
125 patients with radiation therapy—1 survived 5 years and 4 survived shorter periods

Exploration in 133 cases with 100 excised

Operative mortality, 36.1%
5-year survival for those surviving operations, 19.4%

Garlock and Sweet have separately reported a significant series of cases with a 5-year survival record considerably more encouraging

Stomach and Small Intestine

Donald R. Webster, MD

STOMACH

Introduction

Primitive man was probably more aware of his stomach than any other internal organ. All the disturbances in his peritoneal cavity, as well as hunger and satiety, were interpreted by the reaction of the stomach. Despite this, our knowledge has grown very slowly and it has been difficult to correlate physiologic, clinical, and pathologic information. As all good surgery must rest on a sound anatomic and physiologic basis, so gastric surgery has progressed only with advances in such fundamental knowledge.

It was the United States army surgeon, William Beaumont, in 1825, who had the imagination and perseverance to study Alexis St. Martin, the Canadian *voyageur* who developed a gastric fistula from a gunshot wound. This is one of the most fascinating stories in medical experience and laid the foundation of gastric physiology. Beaumont collected gastric juice, described the properties, and recognized the influence of emotions on the circulation, secretion, and motility of the stomach. This fundamental work has its modern counterpart in a monograph by Wolf and Wolff describing their subject "Tom," and confirming and extending Beaumont's original observations. The great Russian physiologist Pavlov devised the innervated gastric pouch, demonstrated the psychic phase of gastric secretion, and proved the vagal pathways

of the stimulus. Many modern physiologists, such as Babkin, a pupil of Pavlov's, Cannon, Carlson, Ivy, and others, have gradually extended our knowledge, but much remains to be done. We do not know exactly how the hydrochloric acid of the gastric juice is formed, why the stomach does not digest itself, how painful sensations in the stomach are transmitted, and why ulcers form and heal in some persons and not in others.

Embryology

The stomach appears in the 4th week of embryonic life as a spindle-shaped dilatation of the primitive gut, caudal to the lung bud. Just distal to this the liver bud appears, and from this two dilatations arise which form the gall bladder and the anterior part of the pancreas (the posterior portion of the pancreas arises as a separate bud). There are both dorsal and ventral mesenteries, the latter, however, extending only as far as the umbilicus. The dorsal border and esophageal end of the stomach grow more rapidly than the pyloric end, and a rotation occurs. The dorsal surface turns to the left, and the ventral and pyloric end to the right, following the growing liver. Thus the ventral side becomes the lesser curvature, the dorsal surface the greater curvature, the left side the anterior surface, and the right side the posterior surface. The vagus nerves follow the rotation so that the left becomes anterior and the right posterior. The dorsal

mesentery forms part of the lesser sac and the great omentum. The ventral mesentery by the growth of the liver forms the lesser omentum and falciform ligament.

Anatomy

The stomach varies in size and shape, and must be viewed with the fluoroscope to visualize the individual differences. The cardia is fairly constantly situated at D12 and the pylorus at L1 or L2. The position of the greater curvature, however, depends upon the shape, content, and tonus of the stomach. The organ is described as steer-horn or J-shaped, and any gradation may occur between these extremes, depending on the habitus of the patient and the tone of the stomach at the time of examination.

Fig 286—Regional anatomy of the stomach

The stomach is divided into cardia, fundus, body, and pylorus. The cardia is the area surrounding the esophageal opening. The fundus extends to the left and about 1" above the level of the cardia and is in contact with the left dome of the diaphragm. The body is limited by the fundus and the incisura angularis. The pyloric antrum is that portion between the incisura and the duodenum.

The wall of the stomach consists of a serosa of peritoneum, three muscular layers, and a mucosal lining. The serosa covers the stomach except at the lesser and greater curvatures, where it separates to form the lesser and greater omenta. Of the three muscular coats, the external longitudinal layer is continuous with that of the esophagus above and the pyloric sphincter below. Its fibers are scarce over the anterior and posterior surfaces. The middle

circular layer covers the whole stomach and ends as the pyloric sphincter. The inner oblique layer is continuous with the circular muscle layer of the esophagus and is well developed over the fundus of the stomach and fans out toward the incisura.

The mucosa covers the whole of the interior of the stomach. There is a gradual change in the character of the mucosa at the beginning of the pylorus which normally requires microscopic differentiation in human beings. Here the peptic glands are normally replaced by the pyloric glands secreting alkaline mucus. The peptic cells are incorporated into compound racemose glands, which contribute a complex product. The goblet cells of the surface secrete the visible mucus, while the neck cells probably secrete the dissolved mucin. The chief cells containing zymogen granules secrete the enzyme pepsin, and oxyntic cells, hydrochloric acid. Scattered through the gland are the argentaffine cells whose function is not known but may be related to the formation of the intrinsic factor of Castle. Over all is a tall simple columnar epithelial layer continuous with the stratified squamous epithelium of the esophagus above and the intestinal epithelium at the pylorus.

Arterial Supply.—The entire blood supply of the stomach comes from branches of the celiac axis. The left gastric artery runs toward the esophagus upon the diaphragm and passes downward along the lesser curvature of the stomach to end by anastomosing with the right gastric artery. The right gastric artery, a branch of the hepatic artery (occasionally of the gastroduodenal artery), passes to the left along the lesser curvature to anastomose with the left gastric artery. The hepatic artery also gives off the gastroduodenal artery which runs below the pylorus and first part of the duodenum and divides into the superior pancreaticoduodenal and right gastroepiploic artery, passing to the left in the greater omentum and giving off branches to the greater curvature. The left gastroepiploic artery, after arising from the splenic artery, supplies the greater curvature and also the greater omentum. Occasionally this artery anastomoses directly with the left gastroepiploic artery, but more often this anastomosis is made through smaller branches. Arteriovenous anastomoses are present and re-

ported to be decreased during secretory activity. Ligation of the majority of the larger arteries will not cause necrosis or interfere permanently with secretion.

Venous Drainage.—This is almost entirely into the portal system. The right gastroepiploic vein drains into the superior mesenteric vein, a tributary of the portal vein, while the gastric and splenic veins empty directly into the portal vein. The vicinity of the cardia and lower esophagus is one of the most important communication areas between the systemic and portal systems. Esophageal varices may develop from any obstruction in the portal and splenic venous drainage.

Nerve Supply.—The stomach is supplied by branches from the parasympathetic system through the two vagi, and from the sympathetic system by branches from the celiac

ganglion that accompany the blood vessels. The left vagus becomes the anterior vagus below the diaphragm, dividing into a number of branches. Some of these fibers anastomose with the right vagus, but the majority supply the anterior wall of the stomach and the lesser curvature. These disappear beneath the serosa and enter into the plexuses of Meissner and Auerbach. The right vagus nerve, now the posterior, sends branches to the celiac ganglion and breaks up to supply the posterior wall of the stomach, pylorus, and probably the whole intestinal tract, through the intrinsic plexuses. The celiac ganglion receives efferent fibers from the greater and lesser splanchnic nerves. Thus the stomach has a double nerve supply. The vagus is the main secretory nerve of the stomach, but in most other functions the two systems act in a reciprocal or occasionally in a supplementary manner.

Lymphatic Drainage.—The lymph gathers into radicles in the submucosa. These pierce the muscles and serosa, forming large vessels which, in general, follow the course of the veins. Thus the lymphatics of the lesser curvature drain away from the pylorus, following the coronary vein to the celiac nodes and communicating in their course with the lower esophageal lymphatics. There are numerous nodes scattered throughout the lesser omentum. The lymphatics on the greater curvature are much fewer in number than those on the lesser curvature. The fundus and upper part of the body drain to the hilus of the spleen, while the lower portion and pylorus empty into the subpyloric group and into the celiac nodes. The lymphatics of the pylorus and duodenum do not communicate, thus hindering the distal spread of malignant disease from the stomach.

Physiology

The stomach in addition to being a reservoir has important secretory and motor functions. The stomach secretes hydrochloric acid which was first identified by Prout in 1821. Despite intense investigation the exact mechanism of its formation is not known but is probably the result of a complicated enzymatic process. The hydrochloric acid concentration of pure gastric juice is about pH 1. It is probable that the parietal cells secrete the acid at the same concentration, and variations in acidity are due to diluting and buffering agents such as saliva, food, and mucus. The function of the acid is to provide an optimum pH for the action of the proteolytic enzyme pepsin. Hyperacidity is due to hypersecretion with less opportunity for dilution. This may also be a reflection of the number of actively secreting cells in response to different types of stimuli. The hypersecretion that occurs in duodenal ulcer is the result of the augmented secretory activity of a "large cell mass." Pepsin is secreted by the so-called chief cells. These lie scattered throughout the body of the gastric gland and in the resting state are full of granules that disappear with secretory activity. Pepsin is probably secreted in an inactive state as propepsin that passes into the lumen of the gland to be activated by the hydrochloric acid. The propepsin is also absorbed into the circulation

and excreted in the urine as uropepsin. This can be measured and is reported to be increased in peptic ulcer cases, especially accompanying exacerbations of ulcer activity.

Mucus is secreted in two forms, a visible material which is a product of the surface epithelium and a dissolved mucus secreted by the neck cells. This latter substance contains a mucoprotein probably associated with the so-called intrinsic factor that combines with vitamin B₁₂ to produce a substance essential for hematopoiesis.

The secretion of gastric juice consists of three phases: cephalic, chemical, and intestinal. The cephalic or *psychic phase* is initiated by the sight, smell, taste, or thought of food. The stimulus passes by the vagus nerves to the gastric glands, and this is abolished by atropine and vagotomy. The secretion produced by vagal stimulation accounts for about one half of the total secretion of the digestive period. It is much richer in enzymes than the secretion resulting from the chemical phase.

Hypoglycemia stimulates the vagal centers, producing a large flow of gastric juice. This is used as a test for completeness of the operation of vagotomy. Insulin is given in sufficient amounts to reduce the blood sugar to at least 50 mg %. If no secretion occurs in the stomach, it can be assumed that all vagal fibers have been interrupted, provided a control test produced a secretion before the operation. The lesser curvature of the stomach has a more active vagal innervation than the greater curvature. Stimulation of the sympathetic fibers has a slightly inhibitory effect on the secretion produced by vagal or chemical means. There is evidence that the vagal stimulus exerts its full action only if the pylorus is intact, and, conversely, chemical stimulation of the stomach is reduced if the vagi are cut. This suggests that there is an interdependence in their activities.

The two succeeding phases are the physiologic sequelae to the psychic secretions. The presence of food in the stomach results in the formation of a hormone (*gastrin*) that produces a flow of juice of high acidity but poor in enzymes. This was considered at one time to be histamine, but Komarov proved it to be a separate entity. The pyloric antrum appears to secrete gastrin mainly in an alkaline en-

vironment, and acid produces an inhibitory effect. Dragstedt has shown that if the pylorus is transplanted to the colon, a copious and continuous secretion from the stomach occurs. Harrison et al. have demonstrated that if a portion of the transplanted antrum is left in continuity with the stomach, the total amount of secretion is reduced but rises again if the remaining portion of the antrum is resected. This would indicate that the pyloric antrum has an inhibitory effect on secretion if in contact with the normal acid gastric juice and thus plays a part in the regulation of gastric secretory activity. This hormone appears to be formed mainly in the mucosa of the pyloric portion of the stomach, and it is for this reason that the pylorus should be removed when doing a subtotal gastrectomy. If it is left, gastrin may continue to be formed, and the resulting secretion from the remaining portion of the stomach will predispose to the formation of another ulcer. A similar hormone though less active (*enterogastrin*) is formed in the duodenum and upper jejunum.

Meat and protein extracts are the strongest stimulants of gastric secretion, while carbohydrates have very little effect. Fats stimulate a secretion of gastric juice while in the stomach but, after passing into the duodenum, stimulate the formation in the intestinal mucous membrane of a substance causing marked inhibition of gastric secretion. This substance has been extracted by Ivy and called "*enterogastrone*." There are other gastric secretory depressants formed in the intestinal tract, and Gray has extracted from the urine of normal persons an inhibitory substance termed *urogastrone*. Whether these substances play any part in the normal regulation of gastric secretion is not known.

It was shown by Gray et al. that ACTH will produce a secretion of gastric juice after a long latent period, following vagotomy and removal of the pyloric antrum, but not after adrenalectomy. Stimulation of the hypothalamus will also produce a secretion that is blocked by adrenalectomy. It has been suggested that this is the mechanism of the production of the so-called *Curling's ulcer*.

A diminished secretion and achlorhydria occur frequently in older persons or in persons with diabetes mellitus or carcinoma of the

stomach. Complete achlorhydria is always present in pernicious anemia. It is also found in some cases of hyperthyroidism, Addison's disease, arthritis, and some of the dermatoses.

The stomach exhibits tone and peristalsis. The tone keeps the stomach wall closely applied to the food mass. The peristaltic waves gradually move the liquefied bolus to the pyloric antrum and into the duodenum. There have been many suggestions as to the emptying mechanism of the pyloric valves, such as the acidity of the duodenal contents or the relaxation before an advancing peristaltic wave.

Fig. 288—Mechanism of the stimulation of gastric secretion

Recent work suggests that the pylorus is normally in a patulous state, and when the stomach contents are sufficiently liquefied and diluted, they pass into the duodenum. The bolus remains for a few moments in the first part of the duodenum, to allow perhaps for neutralization. This area is known as the *duodenal cap* when visualized by x-ray; failure to outline this region or demonstration of a deformity is often due to the presence of an ulcer.

The vagus is usually considered as motor to the stomach and the sympathetic as inhibitory, but either nerve may produce the same motor effect, depending on the state of the organ when the stimulus arrives. No "pacemaker" that initiates or controls peristaltic movements has ever been demonstrated.

Absorption.—Only small amounts of carbohydrate are absorbed from the stomach and no fat. Proteins, although split in the stomach, are only absorbed in negligible amounts. Water, alcohol, and probably hydrochloric acid are readily absorbed.

CONGENITAL ANOMALIES

(See Chapter 30)

TRAUMA, WOUNDS, AND FOREIGN BODIES INVOLVING THE STOMACH

Contusion

The stomach may be contused in association with other organs in crushing injuries. There is usually epigastric pain, blood-tinged vomitus, and rigidity of the abdominal wall. It may be difficult to be sure there is not a perforation, and the patient must be watched carefully. The abdomen should be x-rayed to exclude the presence of free gas in the peritoneal cavity suggesting a perforated viscus.

Rupture

Rupture usually results from a blow to the abdomen when the stomach is full of food or distended with gas. An old ulcer may rupture or a small split occur near the cardia. The signs are those of a perforated viscus, and the patient should be operated upon as soon as conditions permit.

Wounds

Gunshot and knives are the commonest agents producing wounds of the stomach. The direction of the missile can usually be estimated and often there is injury to other viscera. If there is no sign of exit of the missile, its position should be localized with x-ray. Operation should then be carried out, not to remove the bullet, but to repair the viscus, and the surgeon must be prepared to deal with any injuries that may be found in other organs.

Foreign Bodies

Innumerable varieties of foreign bodies have been found in the stomach. They can be generally classified into those swallowed:

1. **Accidentally.** These are usually small and will be passed without trouble, such as needles, pins, buttons, coins, teeth, marbles, etc.

2. **Intentionally.** This usually happens with psychotic patients, professional "sword swallowers," attempted suicides, or those hoping to conceal evidence. Articles removed have included nails, glass, razor blades, toys, money, parchment, hair, etc.

Accumulation of swallowed hair is called a bezoar. Vegetable fibers may become entangled with the hair until it fills the stomach, forming a perfect cast. The symptoms are a sense of fullness and foul breath; pyloric obstruction may ensue.

Occasionally penetration of the stomach wall may occur from foreign bodies in the abdominal cavity or neighboring organ, such as instruments, drains, or gallstones.

Treatment.—If the articles are small they will be passed. It is remarkable how large an object will go through the pylorus and ileocecal valve. Such things as open safety pins, needles, and razor blades should be observed with the x-ray, and if not passing satisfactorily should be removed surgically.

VOLVULUS

This is a rare condition where the stomach rotates about its longitudinal or sagittal axis. Radiologists report that a temporary volvulus is not infrequently seen during fluoroscopy. Many of these cases are described with ulcer, diaphragmatic hernia or eventration, neoplasm, or simple distention of the colon. There may be only symptoms of dyspepsia. In acute cases, however, there is vomiting or nausea with inability to vomit, upper abdominal distention, and collapse. Occasionally a stomach tube cannot be passed. A barium swallow will sometimes show the barium confined to a small pouch in the left upper quadrant.

The treatment of acute volvulus is reduction of the volvulus, examination of the stomach for necrosis, and resection if necessary. If the stomach is intact, fixation of the stomach or colon should be carried out.

INFECTIONS

Acute Infectious Gastritis

An inflammatory reaction of the gastric mucosa accompanies many febrile conditions. It is marked by burning epigastric pain, nausea, and vomiting. Achlorhydria may be present. Occasionally hemorrhage occurs which may be confused with bleeding ulcer. The condition disappears as the systemic condition improves.

Acute Suppurative or Phlegmonous Gastritis

Phlegmonous gastritis is a very rare condition in which a part or the whole of the stomach wall may be involved in an acute suppurative process.

It occurs most frequently in the course of some septic process elsewhere in the body but may follow ulceration or trauma of the stomach. The streptococcus is the commonest organism involved, but staphylococci, pneumococci, and the anaerobic groups have been found.

The process spreads in the submucosa, pus collects, and the whole mucous membrane of the stomach may be shed as a cast. The symptoms are those of an abdominal catastrophe, with agonizing steady epigastric pain, nausea, vomiting, rigidity, high fever, and collapse. Recovery may take place, but death usually ensues due to intoxication, or perforation with peritonitis. The differential diagnosis includes perforation, acute pancreatitis, and cholecystitis. Treatment consists of antibiotics, intravenous alimentation, and drainage of any localized abscess. Healing may be followed by a form of limitis plastica.

Acute Gastritis

Acute gastritis may result from the ingestion of corrosives or highly irritating substances. The extent of the reaction depends upon the corrosive action of the material and varies from congestion and edema to ulceration, necrosis, sloughing, and perforation. If the poison has not resulted in a marked corrosive effect on the pharynx and esophagus, or if its character is known, the stomach should be emptied by lavage or emetics. The appropriate antidote should be administered, fol-

lowed by catharsis. The patient may need circulatory support and sedation.

A milder form, sometimes referred to as exogenous gastritis, may occur with the taking of alcohol, extremely hot or cold beverages, of bacterial products, and some medicines such as quinine, iodine, bromides, etc. The symptoms are epigastric discomfort, burning, nausea, anorexia, vomiting, and diarrhea. Achlorhydria is common in the acute stage, and acidity gradually returns as the condition improves.

Treatment.—Usually vomiting has emptied the stomach. Sedation with an opiate is often required, followed by an antacid mixture. Return to a normal diet should be gradual.

Chronic Gastritis

Since the development of the flexible gastroscope by Schindler and others, gastritis has been diagnosed more frequently. Chronic gastritis may be loosely classified as hypertrophic, atrophic, and mixed types. In the hypertrophic type, the rugae are large and coarse and often the site of erosions that bleed easily. There is proliferation of the interstitial cells and lymph follicles, while the submucosa is fibrosed. Mucus is often secreted in large quantities. In the atrophic type, the mucosa is thin and the glandular elements inactive. The muscle is atrophied and fibrotic. All gradations of the condition may occur, representing different stages of the disease.

It has not been our experience that any widespread gastritis is present in stomachs resected for duodenal ulcer but is frequently present in cases of gastric ulcer. It is common in carcinoma of the stomach, which may account in part for the anorexia, achlorhydria, and epigastric discomfort.

Etiology.—There may be a definite and sometimes prolonged history of ingestion of irritants, notably alcohol, or hot, highly spiced foods, some drugs, or infected material from the nose, throat, or sinuses. It may also follow pyloric obstruction with stasis or anastomotic operations. There may be a neurologic mechanism involved. The atrophic variety is associated with some deficiency states, especially pernicious anemia, when achlorhydria is invariably present.

Symptoms.—These may vary from vague discomfort to an ulcerlike syndrome. The

erosions may bleed, varying from a slight ooze to massive hemorrhage. There may be vomiting, and in cases due to alcohol, the vomitus may contain large quantities of mucus.

Diagnosis.—It is usually made by a careful clinical history and by excluding other lesions by such examinations as x-ray, gastroscopy, and gastric analysis.

Treatment.—Treatment is directed toward removing underlying causes and giving a bland diet. Hydrochloric acid should be given in the achlorhydria cases and antacid mixtures in the hypersecretory ones.

Tuberculosis

Tuberculosis of the stomach is rare and is almost always associated with tuberculosis elsewhere in the body. It may result from swallowed sputum, infected milk, or hematogenous spread from a distant focus. Direct extension from another organ may occur. The lesion may ulcerate or form a tumor with caseation in the submucosa, which may then obstruct the pylorus.

Treatment.—The diagnosis is usually made following a laparotomy. Resection is not advised, and the patient should be treated by supportive measures. The prognosis is poor.

Syphilis

Syphilis of the stomach is very rare and occurs only in patients with active disease. There may be an ulcer, but usually the granulomatous process involves the stomach wall to produce the "linitis plastica" type of stomach. Symptoms usually simulate those of other lesions of the stomach and are not characteristic. The gastric crises of tabes may be a feature. The treatment is that used for syphilis, although at times a total gastrectomy may be indicated.

PEPTIC ULCER (GASTRIC AND DUODENAL ULCER)

Ulcerations of the stomach and duodenum have much in common both etiologically and pathologically but appear to be different entities. They are often termed peptic ulcers and in many respects can be discussed together. They occur only in tissues in contact with acid gastric juice, and therefore they are seen oc-

asionally adjacent to aberrant gastric mucosa such as occurs in the lower portion of the esophagus, in a Meckel's diverticulum, or in an anastomosis of the stomach to the jejunum.

While there are many similarities between duodenal and gastric ulcers, there are also marked differences. In duodenal ulcer there is often a marked hypersecretion of gastric acid with high acidity, whereas with gastric ulcer hypersecretion does not occur to the same extent and may show normal levels of acid.

Fig 289 —Suggested etiologic factors in the formation of peptic ulcers

The patient with a gastric ulcer is not usually the emotional type so often associated with duodenal ulcer. The most important difference, however, is that while malignancy in the part of the duodenum is extremely rare, malignant ulceration in the stomach is extremely common. The exact incidence of malignant degeneration in a gastric ulcer is not defi-

known but is probably in the neighborhood of 7%. Nevertheless, the lesion may be a primary ulcerating carcinoma which requires early surgery if healing is not prompt and permanent.

Peptic ulcer is apparently a disease of modern times. While the older writers occasionally mentioned the symptoms suggestive of peptic ulceration, no definite cases were described until the 18th century, and these were described as unique lesions. In the middle of the 19th century several small series of cases were recorded. These were mostly gastric ulcers. Duodenal ulceration was apparently regarded as a rare disease. From 1900 onward there appears to have been a marked increase in the incidence of peptic ulcers all over the world. Patterson states that 12% of the American population have peptic ulcers at some period of their lives. The site of the ulcer has shifted from the stomach to the duodenum so that duodenal ulcers are about 10 times as common as gastric ulcers and far more common in men than in women.

Etiology.—Peptic ulcer appears to be the result of conflict between constitution and environment. The proponents of the neurogenic concept believe that sustained emotional states cause increased secretion of gastric juice and alterations in the gastrointestinal mucosa permitting digestion of the tissue. Cushing demonstrated that lesions of the midbrain could produce ulceration in the stomach and duodenum, and many psychiatrists think that a similar process is involved in some psychosomatic states. This is the basis for the operation of vagotomy.

Another school, originally led by the distinguished pathologist Virchow, believes that ulceration is a local disease due to some devitalization of the mucosa from trauma, gastritis, foci of infection, allergy, emboli, or vascular change in the wall itself. Bigelow and Keyes have demonstrated that stimulation of the peripheral end of the cut vagus produces sludging of blood in the area of the stomach where ulcers frequently occur, thus adding support to both theories. It has been shown on an experimental basis that an ulcer will occur in response to an increase in acid-pepsin production, inadequate neutralization, buffer-

ing, dilution, or a reduction in basic tissue resistance. There are innumerable theories offered for the causation of ulcer, but most evidence is in favor of increased secretion of acid gastric juice. Numerous attempts have been made to produce experimental ulcers in animals by trauma, chemicals, and the diversion of intestinal secretions or contents. These ulcers are usually acute, and if they do not perforate and nutrition is restored, they will heal readily. One must guard against concluding from this that lesions of the gastric or duodenal mucosa, which can be produced in animals by many different types of insults, have any relationship to the chronic ulcer in man.

Zollinger, in 1952 and 1955, reported hypersecretion and intractable and recurring peptic ulcers associated with an atypical alpha cell tumor of the pancreas. It is supposed that this tumor secretes a gastrinlike substance, producing hypersecretion, or that glucagon is a stimulant to gastric secretion. There seems to be agreement that whatever the fundamental cause, the hypersecretion of gastric juice mediated through the vagus is responsible for duodenal ulceration. Dragstedt believes that gastric ulcers are dependent on the hormonal mechanism of the antrum.

Many lengthy series of ulcer cases have been analyzed, and from these certain features are notable:

1. *Age.* While peptic ulcers have been reported in the very young, duodenal ulceration seldom occurs before 20 years of age, and gastric ulceration still later. The age peak of duodenal ulcers is in the fourth decade, and gastric ulcers in the fifth.

2. *Sex.* Peptic ulcers are about four times more common in men than in women.

3. *Occupation.* In the Western world ulcers are more prone to occur in people with financial and administrative worries.

4. *Constitution and heredity.* Duodenal ulcer patients are usually the high-strung worrying type and appear to have a larger secretion of gastric juice than the normal person, especially the fasting and night secretions. There are numerous instances of peptic ulcers occurring in several members of the same family, which may indicate a predisposition to the disease.

CHRONIC GASTRIC ULCER

PERFORATED GASTRIC ULCER WITH
WALL ADHERENT TO PANCREAS

5. *Diet* There is no specific article of diet that can be proved to cause ulcers. There is some evidence that those who eat highly spiced foods, take alcohol on an empty stomach, and those who cannot properly masticate food are more prone to develop an ulcer. Lack of a food factor such as vitamin B₁₂, as suggested by Semmerville, may play some part. In some regions, such as northern India, peptic ulceration is unknown. Protein deficiency increases the susceptibility to ulcers in the experimental animal, lengthening the gastric emptying time and increasing the incidence of perforation in these ulcers.

6. *Trauma* Peptic ulcers, usually duodenal, occasionally occur in cases of severe trauma or burn and are called "Curling's ulcers." These are probably due to the production of histamine like substances from the traumatized area.

7. *Allergy* There is no direct evidence available that this plays any part in human beings, although previous sensitization increases the incidence of experimental ulcer produced through histamine stimulation.

It is possible that not one but many etiological factors are responsible. There may be a deficiency of some protective substance represented perhaps by *Ly's* enterogastrone or some basic endocrine or enzyme disturbance, such as an excess of lysozyme. Whatever the predisposing and initiating factor, it is the digestive action of the gastric juice that actually produces the ulcers and prevents their healing. This has led to the dictum of "no acid, no ulcer," and the reduction of acidity below the optimum for the action of pepsin has been the aim of the most successful medical and surgical forms of treatment.

Pathology.—Gastric ulcers are usually situated in the pylorus or in the lesser curvature in the region of the incisura, occasionally high in the cardiac region. These are the areas where there are few, if any, acid-secreting cells. Duodenal ulcers are most commonly seen in the first part of the duodenum, frequently so close to the pyloric ring that it is difficult to decide on which side the disease began.

Peptic ulcers may vary from minute erosions to complete destruction of all coats of the wall. The ulcer itself may be shallow or deep, depending on its activity. The edges

may be slant shelving, or undermining. The base of the ulcer becomes indurated and covered with fibrinous exudate over which a gray slough can be seen. In large ulcers the base is often covered by islands of mucous membrane. If situated anteriorly, the ulcer may erode through the wall; but the pancreas becomes involved and the base of the ulcer. If the ulcer is situated in the anterior wall, perforation may occur into the peritoneal cavity, or it may become adherent to surrounding structures such as the liver or gall bladder. Bleeding may be minimal but if a large vessel is eroded, serious or fatal hemorrhage may occur.

In chronic ulcers there is always an inflammatory area surrounding the lesion, especially at the base. This may be marked with edema and induration. Vascular disturbances occur with thrombosis and obliteration of the arteries. Evidence of healing can often be observed by proliferation of the epithelium at the edge of the lesion and production of granulation tissues in the base.

In the healing process cicatrization may cause serious complications. Those of the lesser curvature may give rise to "hourglass" stomach and those near the pylorus to obstruction preventing the emptying of the stomach.

Clinical Picture.—Pain is the most distressing feature of peptic ulceration. It may vary from a feeling of slight discomfort to a gnawing, burning ache that intrudes into the daily life of the victim and disturbs his rest at night. It can produce a facies depicting suffering and change a person into a hopeless hypochondriac. In the early stages of the disease the location of the pain is indefinite, but if long-continued and an inflammatory reaction is present, the gastric ulcer pain is in the mid-epigastrium and that of duodenal ulcer to the right of the epigastrium.

The pain of duodenal ulcer appears some 2-3 hours after a meal and is relieved by the taking of more food or alkalis. This sequence was described as the "ulcer rhythm" by Moynihan, who epitomized it as gastric ulcer—food, comfort, pain, comfort; and duodenal ulcer—food, comfort, pain. The pain is seldom typical, however, and symptoms may be indefinite.

Sometimes the pain is accompanied by belching, nausea, and occasionally vomiting, which

may relieve the pain. There is frequently a seasonal periodicity to the symptoms, increasing in the spring and autumn, and also a poorly understood individual rhythm, where the patient may be completely free of pain for weeks or months. These are usually periods of transient healing when the crater may disappear in the x-ray picture. Attacks may be precipitated by worry, fatigue, alcoholic beverages, and excessive smoking, and also by certain specific foods, especially coarse vegetables and fried food, which the patient soon learns to avoid. Realizing that food or alkalies will relieve the pain, he often carries some medication with him and to his bedside at night.

stomach is empty. Many investigators have attempted to correlate the hunger contraction of the stomach with the waves of pain in ulcer, but again the relation is not consistent. Others feel that ulcers are only painful when an inflammatory reaction is present. The instant relief produced by vagotomy may be explained by a diminished secretion of gastric juice or the reduction in the motor activity of the stomach.

Physical Signs.—There are no definite physical signs, but ulcer patients are frequently, though not always, thin, having lost weight through a self-imposed diet. The face occasionally portrays suffering or irritability.

Fig 290.—Diagrammatic comparison between the distribution of peptic ulcers and the location of peptic and pyloric glands

When the ulcer is active and penetrating anteriorly toward the serosa or posteriorly toward the pancreas, the pain is usually aggravated and assumes a boring, gnawing character which may become continuous, unrelieved by food. This may suggest a dangerous change in the activity of the ulcer, often indicating a progression of the penetration. The mechanism of this pain is not satisfactorily explained. There are many factors that may influence the sensation of pain, such as the size and location of the ulcer, the degree of penetration, the involvement of adjacent structures, and the pain threshold of the patient. However, the explanation of the pain in uncomplicated ulcer is not satisfactory. Theories such as the contact of hydrochloric acid with the ulcer surface do not explain the presence of pain when the

Pallor may be present if bleeding or malnutrition has been prolonged.

Locally there is usually hyperesthesia over the epigastrium and tenderness on deep palpation. There may be some guarding of the muscles over the ulcer and tenderness over the lower dorsal vertebrae, particularly if the ulcer has involved the pancreas or posterior abdominal wall. If pyloric obstruction is present, a succussion splash can be elicited and visible peristalsis observed.

The palpation of a mass suggests a marked inflammatory reaction about a penetration, and malignancy must be excluded.

Diagnosis.—A careful history and observation of the patient are often adequate to suggest the diagnosis, and confirmatory in-

vestigations can be carried out. Laboratory aids are most helpful, and with their proper utilization a high percentage of correct diagnoses can be obtained.

X-ray studies by means of a barium meal furnish the most useful diagnostic weapon we possess. These yield information about the

lesion, if in the stomach, although the "blind areas" of the fundus limit its usefulness.

Gastric Analysis.—The examination of the stomach contents is at times a valuable aid in establishing a diagnosis. A tube is introduced into the stomach, and the fasting contents are withdrawn. If the volume is large, or if there

Royal Victoria Hospital Gastric Analysis

Fig 291—Sample chart of normal gastric analysis

size and location of the ulcer, the patency of the pylorus, the dilatation of the stomach, the deformity of the duodenal cap, or the presence of polyps or diverticula

Gastroscopy—The gastroscope in the hands of experienced observers will frequently demonstrate the site and the character of the

are remains of food taken many hours previously, it is evidence of pyloric obstruction. A test meal of either food or alcohol, which is seldom used now, or a chemical such as histamine or insulin is given, and the contents are aspirated every 15 minutes for 2-3 hours afterward.

The acidity and volume are measured; the presence or absence of blood is determined, and if there is a suspicion of malignancy, a cytologic examination can be carried out. Large quantities of mucus suggest gastritis. If bile is present, the pylorus must be patent. The acidity and volume are usually higher in duodenal ulcer than in gastric ulcer cases, and very high levels suggest an active duodenal ulcer. The absence of free hydrochloric acid or a low acidity in the presence of a gastric ulcer is suggestive of malignancy.

Occult Blood—This is usually positive in all active ulcers.

Treatment.—Surgery is required for those cases of ulcer that resist medical treatment and where complications make it imperative. In uncomplicated ulcer, persistent pain despite adequate rest, diet, and medication is the symptom for which the patient demands relief. Every case, however, must be individually studied. The patient's background, his home, habits, and occupation must be reviewed to eliminate any adverse factors if a high percentage of success is to be attained.

Gastric ulcers, especially in the prepyloric area of the stomach, require surgery if after 3 weeks of intensive medical therapy the ulcer is not completely healed clinically and radiologically. This is necessary because carcinoma develops in 75% of benign gastric ulcers and also because in many cases it is impossible to distinguish benign from malignant ulcers without laparotomy and histologic study.

Gastric ulcers situated near the cardia offer a difficult surgical problem. Their excision with a so-called proximal gastrectomy may be a technically formidable procedure. Dragstedt has suggested that such cases should first have a gastrotomy and a biopsy taken. If the rapid histologic section shows no evidence of malignancy, a low gastrectomy is carried out, including all the antrum. Once the antral factor has been eliminated, the ulcer should heal. It is too early to give an evaluation of this procedure.

The treatment of uncomplicated duodenal ulcer, since malignancy is rare in this area, is primarily medical. Eighty-five per cent of patients respond to adequate medical therapy, thus leaving approximately 15% requiring surgery because of intractability. In both gastric

and duodenal ulcers, surgery is indicated for treatment of the complications, mainly perforation, bleeding, and obstruction. The medical therapy must include correct diet, sedation, antacids, antiparasymphathomimetic drugs, if indicated, and attempted control of home and work environment.

The surgical procedure is planned to remove the lesion where possible and to reduce the acidity to a point where peptic activity cannot take place. Gastric surgery has undergone a long and tedious development, sometimes on a trial-and-error basis, following advances in our knowledge of gastric physiology. The earliest operations attempted closure of perforations. The next step was to direct the gastric contents into the jejunum because the pylorus was stenosed or to prevent the contact of chyme with the duodenal ulcer.

Anterior gastroenterostomy was described by Wolfier in 1881, and posterior gastroenterostomy by Von Hacker in 1885. The immediate results of the operation were good, but a high percentage of recurrence followed after some years. Billroth, in 1881, performed the first partial gastrectomy, uniting the open ends of the duodenum and stomach. As this was not always feasible, he later anastomosed the jejunum to the posterior surface of the stomach. These are commonly spoken of as the Billroth I and Billroth II operations. Later, in 1911, Polya demonstrated his method of anastomosing the jejunum directly to the open end of the resected stomach. This left too large a stoma, and various techniques for reducing the size of the opening and fashioning the anastomoses have been described by Balfour, Finsterer, Hofmeister, and many others.

In cases of pyloric stenosis, pyloroplasties were performed by several surgeons whose methods still bear their names, such as Finney, Heineke, and Mikulicz. These operations alone have now been abandoned in the treatment of peptic ulcer. Ligation of the majority of the gastric vessels was advocated by Wilson Hey but has received little support in this country.

Recently several series of Billroth I procedures have been reported by Harkins, Tanner, and others. When technically possible, it would seem to offer a more physiologic restoration of the food pathway. Tanner, however, has reported several recurrent ulcers. Henley,

who interposed a length of jejunum between the resected stomach and duodenum, has reported a similar experience.

We believe the operation of choice is a subtotal gastrectomy of the Hofmeister-Finsterer type, removing about three quarters of the stomach, including the pylorus, and the ulcer site in the duodenum. The anastomosis is made posteriorly with a short loop of jejunum fixed high on the stomach so that angulation will not occur and with a stoma that will admit about two fingers. This procedure removes a larger portion of the fundus with its parietal cells, as well as the antrum with its local secretion and the hormonal mechanism. This reduces the stomach's production of acid while the flow of alkaline pancreatic and biliary secretions through the gastrojejunostomy further decreases the acidity of the gastric contents emptying into the jejunum. Occasionally, due to adhesions or activity, the ulcer cannot be removed, and a procedure involving removal of the pyloric mucosa has been recommended by Finsterer. This is known as an *exclusion operation*. In such difficult cases, however, a vagotomy and gastroenterostomy are safer. The mortality in gastrectomy usually results from a leaking duodenal stump, and the less radical procedure will often effect a cure.

Vagotomy, either thoracic or subdiaphragmatic, disconnects the stomach from cerebral stimuli, thus abolishing the psychic phase of gastric secretion and reducing motility. Because of this latter effect and because there is often some degree of pyloric stenosis, it is advisable to do a gastroenterostomy at the same time to assist in evacuation of the stomach. Some surgeons are combining partial gastrectomy with a subdiaphragmatic vagotomy. Vagotomy is not recommended for gastric ulcer because of the possibility of malignancy. There is still some dispute as to the ultimate results of vagotomy. Some observers report a marked disturbance of gastric and intestinal motility that worsens with time. However, in other centers the results appear satisfactory if combined with gastroenterostomy, and it is adopted as the procedure of choice in uncomplicated duodenal ulcer.

Dragstedt reported that in patients with duodenal ulcers the fasting nocturnal secretion

of gastric juice is 3-4 times that of the normal and that there is about twice as much acid secreted in response to histamine. He found that after complete vagotomy, the response to insulin hypoglycemia is abolished, the response to histamine decreased 60-80%, and the fasting secretion of hydrochloric acid is reduced to 20% of its previous level.

Sara Jordan, reporting for the American Association of Gastroenterologists after a thorough review of several thousand cases, states that subtotal gastrectomy alone or combined with vagotomy has produced somewhat better results in controlling peptic ulcer than gastroenterostomy combined with vagotomy or vagotomy alone. In all cases reviewed the addition of vagotomy to gastric resection has not improved the subjective or objective results of ulcer treatment.

We believe that vagotomy alone should be reserved for the treatment of gastrojejunal ulcer. It is recommended in conjunction with gastroenterostomy in cases where the ulcer is involved in an inflammatory mass where the removal and closure of the duodenum would be hazardous. It may be useful in conjunction with subtotal gastrectomy in the occasional young subject with an abnormally high pre-operative acidity.

Complications

The most serious complications of peptic ulcers are perforation, obstruction, and hemorrhage, and in the case of gastric ulcers, malignant degeneration.

Perforation

An ulcer that has penetrated through all coats of the organ is said to have perforated. This may occur slowly, and the inflammatory reaction about the lesion produces adhesions between it and the neighboring organs, so that general peritoneal soiling does not take place, and the adjacent tissue becomes the base of the ulcerative process. This is more likely to occur in posterior duodenal ulcers where the pancreas and posterior abdominal wall may be involved. In anterior ulcers, the liver, gall bladder, or omentum may be the adherent organs. This process is sometimes referred to as subacute perforation. To differentiate such

ulcers from the acutely perforated ones, the term penetrating ulcer is frequently used.

Occasionally a few drops of gastric contents may escape, giving symptoms of acute perforation that rapidly improve, or if posteriorly, may form an abscess in the lesser sac. This is inaptly referred to as chronic perforation.

Acute Perforation.—Acute perforation of an ulcer into the general abdominal cavity is one of the most dramatic of abdominal catastrophes. Frequently, without warning, sometimes following aggravation of ulcer symptoms, the patient is seized with agonizing epigastric pain that soon spreads over the abdomen. He lies on his back with his knees drawn up, the face pale, glistening with beads of perspiration, and sometimes cyanotic. The patient often vomits. The temperature is subnormal, and the pulse is small but not usually over 100. The breathing is entirely thoracic and when one examines the abdomen, it is typically scaphoid, rigid or "boardlike," and tender. The tenderness may be more marked on the right side. X-ray or percussion usually reveals pneumoperitoneum, and the liver dullness is obliterated.

The initial shock usually passes off and the general condition and symptoms improve. The pain is eased, color improves, and the pulse is stronger. The abdomen, however, remains rigid and tender, and the respirations shallow. This is referred to as the stage of reaction which soon merges into that of general peritonitis with distention, hiccough, vomiting, and intestinal paralysis.

If the condition of the patient or circumstances do not permit immediate operation, the stomach should be kept empty by continuous suction, intravenous fluids should be given, and the pain controlled by sedatives. As soon as possible an attempt should be made to close the perforation. It is remarkable that about one third of the patients who have had a perforation repaired by simple closure have no further ulcer symptoms. When the operation is performed within 6 hours of the perforation, subtotal gastrectomy may be carried out, obviating the necessity of a subsequent operation for persistent ulcer symptoms. The treatment of perforation by suction alone should be attempted only by a team skilled in maintaining continuous drainage.

Pyloric Obstruction

As most ulcers are near the pylorus on either the duodenal or stomach side, obstruction may result from spasm, edema, or cicatricial contraction in the healing process. As obstruction develops, the pain is not relieved by food or alkalis, and vomiting becomes a prominent symptom, the vomitus often containing food eaten many hours before.

Dilatation of the stomach is a stimulus to secretion, and the resultant hypersecretion lost to the body because it cannot be reabsorbed results in alkalosis, hypochloremia, and azotemia. X-ray with barium will demonstrate the dilatation and retention.

Continuous aspiration of the stomach contents and the administration of antispasmodic drugs will sometimes relieve the obstruction, indicating that it is due to spasm or edema. If obstruction persists, it is probably due to fibrotic contraction, and complete stenosis is an absolute indication for operation.

Hourglass Contraction

This deformity, dividing the stomach into two cavities, is due to a gastric ulcer, usually involving the lesser curvature. Previous perforations and perigastric adhesions or spasm may occasionally play some part, but the great majority are the result of reaction about a large, lesser curvature ulcer that involves both walls of the stomach—the so-called saddle ulcer. The fibrosis gradually produces a contraction that reduces the gastric pathway to a narrow channel close to the lesser curvature. The symptoms are usually those associated with the ulcer, although fullness, nausea, and regurgitation may be present.

Hemorrhage

Hemorrhage varies from a slight ooze that can be detected as "occult blood" in the stools to a profuse hemorrhage that can be fatal. Small amounts of blood lost continuously may produce a secondary anemia, although this is unusual in ulcer cases.

Frequently the ulcer symptoms are aggravated before hemorrhage occurs and almost completely relieved afterward. This probably represents increased activity and congestion

may vary from a slight ooze to severe hemorrhage. Systemic signs of acute inflammation may be present, and occasionally the inflammatory mass can be palpated.

Diagnosis.—This is made on the history and demonstration of the ulcer by x-ray.

Treatment.—If the symptoms are not controlled by a strict medical regime, operation becomes necessary. The most popular method today is a vagotomy, because if successful it eliminates the more hazardous procedure of a secondary gastrectomy. This latter operation may be very difficult if a primary posterior anastomosis has been carried out

brought into proper nutritional balance, and if conditions permit, a primary radical resection is carried out. If inanition is marked, a loop colostomy proximal to the lesion will lessen the diarrhea and usually result in marked improvement in the patient's weight and general condition. The curative procedure is accomplished by freeing the colon from the mass and either closing the fistula or resecting the involved portion. The gastrojejunostomy is then undone and the involved area of the small bowel is resected. This is followed by a higher gastrectomy and a new gastrojejunostomy.

Fig 294—Gastrojejunocolic fistula

Gastrojejunocolic Fistula

Gastrojejunocolic fistula, as the name implies, is a fistulous connection between the stomach, jejunum, and transverse colon. Except in the rare case where a gastric ulcer perforates into an adherent colon, it is a complication of gastrojejunal ulceration. The colon and enterostomy site are usually bound together in an inflammatory mass, and the fistulous openings are quite close to one another.

Symptoms.—The symptoms are loss of weight, marked diarrhea, foul eructations, and occasionally true fecal vomiting. The diagnosis is confirmed by a barium enema and a barium meal. Both should be done as there may be a valvelike action in one direction that prevents proper demonstration of the lesion.

Treatment.—Medical treatment is of no avail, and the patient will die of inanition unless surgical measures are taken. The patients, who are usually in poor condition, are

Dumping Syndrome

Under the heading of dumping syndrome is grouped a variety of symptoms that may occur after subtotal gastrectomy. These include *vasomotor symptoms* such as muscular weakness, vertigo, flushing, palpitation, sweating, and/or fainting, and *gastrointestinal disturbances* such as epigastric pain, nausea, vomiting, distention, and/or diarrhea. The etiology is not definite but some of the agencies suggested are the following:

- 1 Distention of duodenal loop
- 2 Hypoglycemia
- 3 Traction on mesentery
- 4 Rapid emptying of the irritative gastric contents into the duodenum
- 5 Rapid shift of electrolytes, with potassium deficiency
- 6 Functional

None of these explain all cases. Symptoms usually appear a few weeks after operation and tend to disappear after some months. It is stated that there are fewer cases after a Billroth I anastomosis than after a Polya type of operation. The conversion of a Polya to a Billroth I anastomosis either directly or by the interposition of a jejunal loop has been reported to alleviate the symptoms. Eating a high protein, low carbohydrate diet, with restriction of fluids at meals, and lying down immediately after eating control most symptoms and signs of the dumping syndrome.

CARCINOMA

Carcinoma of the stomach is responsible for one fifth to one quarter of all cancer deaths

It is one of the most frequent of all malignant growths. Livingstone and Pack in 1939 stated: "There are more deaths from cancer of the stomach than from all malignant tumors of lip, tongue, cheek, tonsil, pharynx, larynx, salivary glands, thyroid, male and female breast, ovary, uterine cervix, and corpus uteri combined." It is rare in childhood, uncommon in early adult life, and almost twice as frequent in men as in women. Its insidious growth and trivial symptomatology in the early stages postpone the inevitable visit to the doctor, and even then the frequent vagueness of the complaints often results in palliative treatment for some time before the tragic presence of advanced carcinoma is demonstrated. Until every case of dyspepsia in patients over 35 years of age is suspected, and is examined radiologically, there will be little improvement in our results.

Etiology.—The cause of cancer of the stomach, like cancer elsewhere in the body, is quite unknown. Although heredity and familial predisposition to cancer are suggestive, a causal relationship is statistically difficult to prove. It is essentially a human disease. While other forms of cancer are common in animals, gastric cancer is almost unknown. McCoy examined the gastrointestinal tract of 100,000 rats without finding a single neoplasm. In 381 baboons only one adenoma was found, and it is reported that no case of gastric carcinoma has been found in the enormous amount of material observed in the Chicago stockyards. This marked difference between man and the lower animals has never been satisfactorily explained.

There are geographic and racial differences in the incidence of gastric cancer, but after many studies Pack and McNeer conclude that on the basis of our present knowledge diet offers few clues to the cause of gastric cancer.

The production of adenocarcinoma of the stomach in animals has been very disappointing. The carcinogenic hydrocarbons, deficiency diets, endocrines, parasites, bacterial products, and viruses seem to have no action.

There are, however, three conditions that should be considered precancerous or precursors of cancer of the stomach. These are gastric ulcer, gastritis, and some benign tumors, especially polyps.

Gastric Ulcers.—It has been conclusively demonstrated that cancer may develop in a benign chronic gastric ulcer. It is difficult to estimate the percentage, but it is probably not high. Many ulcers thought to be benign are found to contain cancer cells, when studied after removal. Finsterer reported a series where this was found to be about 20%. It is for this reason that any gastric ulcer that does not heal completely or recurs should be resected.

Gastritis.—While definite proof is lacking that gastritis is a precursor of cancer, the atrophic form of gastritis with achlorhydria, has a higher incidence of cancer than the normal or hypersecreting stomach.

Polyps.—Polyps of the stomach usually occur in association with achlorhydria, and cancer-in-situ has been frequently found in them. While the malignant degeneration is not so apparent as in rectal polyps, they must be regarded as precancerous in a certain number of cases.

Pathology.—Two thirds of gastric cancers arise in the prepyloric area. The lesion generally stops short of the pylorus proper, and invasion of the duodenum is rare. Cancer of the lesser curvature is next in frequency and may arise high in the region of the cardia. Only 5% of gastric carcinomas occur on the greater curvature, but ulcers situated in this area are almost always malignant.

Gastric carcinoma can be divided into four main groups.

1. The ulcerative form is the commonest and arises in the pyloric area or lesser curvature. It varies considerably in size and depth and characteristically has a hard everted edge with a dark red necrotic base which bleeds easily. Microscopically the groups of epithelial cells lie imbedded in abundant fibrous tissue. Infiltration tends to be rapid, although the muscle coat is seldom completely destroyed. The neighboring lymph nodes are invaded very early. It may begin in an apparently normal stomach or at the edge of a chronic peptic ulcer.

2. The papillary or polypoid form is less common and presents as a sharply limited soft mass, projecting into the lumen of the stomach near the pylorus. It may represent malignant degeneration of a benign polypoid

lesion Enlargement is rapid, and ulceration of the mucosa occurs early. As the tumor outgrows its blood supply, necrosis and infection may follow. Microscopically it is an adenocarcinoma but may assume the so-called encephaloid form with scanty stroma and spheroidal cells. It spreads slowly, and may remain localized to the mucosa for a long time.

3. In the infiltrating type a fibrous thickening chiefly in the submucous and subserous coats may cause a stenosis of the pylorus. As the process extends, the body and finally the whole stomach may be involved. It is to this latter type that the term *linitis plastica* or *leather-bottle stomach* has been given. Ulceration may be present but is superficial. Microscopically it is a scirrhous cancer. Metastases are infrequent and occur late, and this form offers a better prognosis than the other neoplastic lesions of the stomach.

4. Colloid or mucoid carcinoma is an adenocarcinoma but contains large quantities of mucus. It usually appears in the pyloric region, giving a gelatinous appearance to the thickened wall. It soon infiltrates the wall, producing colloid cancer of the peritoneum and the so-called "Krukenberg tumor" described below.

Spread.—Cancer of the stomach spreads by direct extension in the stomach wall and to neighboring organs, by the lymphatics, and by the blood stream. Since most carcinomas occur along the lesser curvature, the lymphatic drainage is to the coronary, hepatic, and pyloric groups of nodes. As the disease progresses, more lymphatics are invaded, creeping along the vessels to the celiac axis to eventually involve the aortic group and the nodes in the hilus of the liver. Occasionally spread from the celiac nodes may occur along the thoracic duct or by way of other mediastinal lymphatics to give rise to metastases in the supraclavicular area (Virchow node). Invasion of the blood stream by malignant emboli may set up metastatic foci in the liver, lungs, bone, and brain in that order of frequency, but this is usually late. Lymphatic involvement of the liver is usually of a spreading pattern from the hilus, while blood-borne metastases are scattered and often numerous.

Extension to the pancreas, liver, colon, and omentum may occur when the growth finally

penetrates the wall of the stomach. This is a late sequel, as the serosa appears to offer considerable resistance to the direct spread. Serosal involvement also sets cells free in the peritoneal cavity which may find a foothold on any peritoneal surface. The ovary appears to be particularly susceptible to transperitoneal implantation, producing a bulky secondary ovarian lesion (Krukenberg tumor) characterized by a mucoid cellular degeneration with displacement of the nucleus to form the "signet ring" appearance. If the cells lodge on the pelvic peritoneum, the so-called *rectal shelf* is formed, which can be felt on rectal examination.

Symptoms.—Unless the growth bleeds, or being near the cardia or pylorus causes obstructive symptoms, cancer of the stomach is remarkably free of symptoms. In a mass survey recently reported, Morgan concludes that a much longer asymptomatic period exists than was formerly suspected, lasting perhaps 3 years before the first mild symptoms of indigestion occur. It is for this reason that the onset of dyspepsia, commencing in a patient over 40 years of age who has been previously well, must be regarded as cancer until this has been disproved. Early symptoms are commonly a diminution in appetite and a feeling of distention after a meal. Recurrent attacks of nausea may occur. Pain is late and may be similar to that of peptic ulcer. Insidious hemorrhage usually gives rise to lethargy and pallor, although massive bleeding may occur with a hematemesis or melena. Vomiting is uncommon in the early case unless there is obstruction to the pylorus, while with lesions in the cardia dysphagia is a prominent symptom. Only too often, however, these early symptoms are overlooked until marked cachexia and a palpable epigastric mass place the cancer in the incurable category. Any patient therefore who has dyspepsia, loss of weight, or anemia occurring at or beyond middle age must have a complete examination of the stomach to exclude carcinoma, if he is to be saved by adequate surgery.

If there is a malignant degeneration in a previously benign gastric ulcer, there is a rather sudden change in the dyspepsia. The periodicity of the pain is lost, it becomes more persistent, and is not relieved by food and

alkali. In a series of cases analyzed at the Royal Victoria Hospital it was shown that the longer the duration of symptoms before treatment was sought, the longer the ultimate survival. This finding means only that the growth was very slow-growing and should not have any bearing on treatment. The following chart shows the signs and symptoms in order of frequency in which they occurred in this series.

SIGNS AND SYMPTOMS IN ORDER OF FREQUENCY OF OCCURRENCE

SYMPTOMS	NO	%
Loss of weight	296	69
Abdominal pain (epigastric distress)	289	67
Vomiting	168	39
Abdominal tenderness	144	33
Anorexia	123	28
Epigastric mass	120	28
Weakness	95	22
Pallor	85	19
Abdominal fullness	70	16
Nausea (alone)	68	16
Constipation	63	15
Cachexia	61	14
Gas eructations	53	12
Dysphagia	35	8
Acute bleeding (vomiting of bright, red blood)	15	3
Tarry stools	50	11

Special Diagnostic Measures.—

Gastric Analysis—In approximately half the cases of cancer there is an achlorhydria or hypochlorhydria. However, the remaining cases show free hydrochloric acid within the normal range.

Gastroscopic Examination—In experienced hands the use of the gastroscope, which allows visualization of the tumor, makes the diagnosis certain in a percentage of cases and may also serve to exclude the diagnosis of cancer. However, the gastroscope has three blind spots, the fundus, the pylorus, and the greater curvature opposite the cardia, which greatly limits its usefulness. A negative gastroscopic examination therefore does not exclude the presence of carcinoma.

Occult Blood—This is often positive, and the test should never be omitted in any gastrointestinal investigation.

Roentgenography—Careful radiologic examination of the stomach with particular attention to the mucosal pattern will demonstrate

the carcinoma in a high percentage of cases. However, repeated examinations may be necessary as the tumor may not be visualized in early cases.

Cytologic Examination—Cancer cells in stomach washings may be detected by special stains. Brushes or abrasive balloons passed to the site of the suspected lesion under fluoroscopic control remove the superficial cells into the lumen of the stomach from which they are aspirated. This method has not as high an accuracy as x-ray examination but is a useful adjunct.

Electrogastrography—An electrode is placed by means of a 2 mm. plastic tube into the lower half of the stomach and the other electrode attached to the skin of the arm as a reference. By this means Morton has shown that carcinoma of the stomach gives a characteristic electric pattern, irregular in amplitude and rhythm and different from benign gastric or duodenal ulcer.

Treatment—The treatment of cancer of the stomach is entirely surgical. While past results have not been too encouraging, the survival rate is gradually rising due to improved technique and the widening of the criteria of operability. However, no large gain will be made until cases are diagnosed and treated earlier.

In a study of 427 consecutive patients with gastric carcinoma admitted to the Royal Victoria Hospital from 1941-1950, the operability and survival rate was summarized as shown below.

EXPLORATION—RESECTION—SURVIVAL
(STUDY OF 427 CASES)

Total number of cases	100%
Explored	82%
Resected	38%
Survived resection	34%
Survived 5 years	11.7%
Survived 5 years (corrected for age)	13.6%

Surgical treatment may be roughly divided into (1) resection for cure, and (2) resection for palliation.

The first may be a subtotal resection, removing the greater and lesser omenta and lymphatics, including all visible disease, or it may be a total resection including all involved areas. The second may be palliative, i.e., a

resection, a gastroenterostomy, or even a total resection to enable the patient to empty or fill the stomach and at least make himself more comfortable. It is frequently of value even in the presence of involved lymph nodes or liver metastases.

Many patients with palliative resections do not die of recurrence in the remaining pouch but of local or distant metastases. They are relieved of the obstruction and the presence of a sloughing lesion within the stomach. They may escape hemorrhage or progressive anemia and the effects of septic absorption from the ulcerating mass and obstruction if the tumor is near the pylorus.

If the lesion is situated in the cardia or proximal portion of the stomach, it may extend into the esophagus. The operative procedure of choice is resection of the lesion with at least 5 cm. of normal tissue, including the lesser curvature, and an esophagogastrostomy. This can be done through a thoracic or thoracoabdominal incision.

Lesions in the distal portion of the stomach are best treated by a subtotal gastrectomy, including the first part of the duodenum. It has not been proved that total gastrectomy gives a longer survival than the less radical procedure. Moreover, patients with total gastrectomies frequently present severe nutritional problems and are difficult to rehabilitate to a useful life.

Total gastrectomy is indicated for patients with extensive involvement such as linitis plastica, if there are no generalized metastases.

Wangenstein and others have been practicing re-exploring patients after some months and removing any accessible metastatic nodes. Radiation has not been found to be of value as treatment. It is apparent that only early diagnosis and aggressive surgery will improve the prognosis of the cancer victim.

BENIGN TUMORS

Such growths are uncommon and consist of adenomatous polyps which may be single or multiple. Submucous lipoma, fibroma, neurofibroma or myofibromas may occur. Pancreatic rests are occasionally found in the gastric wall near the pylorus.

Adenomatous polyps may undergo malignant changes, usually beginning at the periphery of the polyp. Tumors arising from the nerve sheaths are the neurolemmas and the neurofibromas, the latter sometimes being associated with generalized neurofibromatosis. Giant hypertrophy of the epithelium may occur, giving the appearance of polyposis. Hypertrophy of the pyloric mucosa may act as a valve producing intermittent pyloric obstruction. The symptoms are usually vague epigastric discomfort, signs of obstruction and hemorrhage. Achlorhydria may occur. The treatment is surgical removal, and total gastrectomy may be necessary in cases of diffuse polyposis.

SMALL INTESTINE

DUODENUM

The name *duodenum* is derived from the approximate length of this portion of the bowel, the breadth of twelve fingers. It extends from the pylorus to the ligament of Treitz making almost a complete loop. It is arbitrarily divided into four portions.

The first or superior portion, called by the radiologists the bulb or cap, is related above to the neck of the gall bladder and the under-surface of the liver.

The second part descends from the 1st to 3rd lumbar vertebra, forming a curve about the head of the pancreas. It receives the common bile duct and main pancreatic (Wirsung) duct in the ampulla of Vater, and the accessory pancreatic (Santorini) duct about 1-3 cm above this. Posteriorly it rests on the right kidney, renal vessels, ureter, and psoas muscle.

The third portion crosses transversely to the 3rd lumbar vertebra where, as the fourth part, it turns abruptly forward to join the jejunum. This junction is supported by the ligament of Treitz. Posteriorly it is related to the vertebra, aorta, and left renal vessels.

Blood Supply.—The superior pancreaticoduodenal from the gastroduodenal branch of the hepatic artery anastomoses with the inferior pancreaticoduodenal, a branch of the superior mesenteric artery. These vessels run along the concavity of the duodenum, giving off numerous branches to the anterior and pos-

terior surfaces. A separate branch from the gastroduodenal or the hepatic artery supplies the duodenal cap.

Innervation.—The duodenum, like the rest of the gastrointestinal tract, is innervated with sympathetic and parasympathetic fibers through the splanchnic and vagi nerves. These pass to the bowel in the coats of the blood vessels and probably act in a reciprocal fashion. Distention of the duodenum produces nausea and pain referred to the epigastrium.

Motility.—The duodenum exhibits peristalsis and rhythmic segmentation. The gastric peristaltic waves usually stop at the pylorus, but Ivy has described them as passing over to the duodenum. Reversed peristaltic waves are commonly seen with the duodenal contents regurgitated into the stomach.

Secretion and Absorption.—The duodenal mucosa, like that of the small intestine, has the remarkable ability to secrete and absorb simultaneously. Substances such as water, alcohol, and glucose are rapidly absorbed in isolated loops, but it is questionable whether this plays much part under normal conditions. Besides the digestive enzymes, the duodenum secretes such hormones as secretin, a form of gastrin, and other substances affecting the gall bladder, the regulation of gastric secretion and hematopoiesis. These have not been completely elucidated.

Congenital Anomalies

Stenosis and Atresia.—These conditions may occur in any part of the duodenum, and the symptoms of high obstruction appear shortly after birth. If the stenosis is below the ampulla of Vater, the vomitus will contain bile.

Malrotation.—These anomalies have been grouped under three headings:

1. Duodenum dextra. This is usually associated with failure of rotation.
2. Duodenum mobile. This is a persistence of a duodenal mesentery to any or all parts of the duodenum.
3. Duodenum inversum. Here the second portion curves upward to the left.

These conditions are found in the course of investigation for other conditions. It is doubtful that many cases cause symptoms, but

when such occur, they result from partial, intermittent obstruction, with crampy upper abdominal pain and vomiting of bile-stained material.

Bands and Membranes.—These peritoneal folds extend from the gall bladder and under-surface of the liver to the proximal portion of the duodenum. Such a fold is sometimes called Harris' membrane. Occasionally the membrane passes to a point below the duodenum, compressing it, giving symptoms similar to stenosis. This occasionally occurs in infants and results in early vomiting of green-colored material.

Diverticula.—These are out-pouchings usually from the second or third portion of the duodenum. They may be true diverticula, involving all coats of the bowel, or the longitudinal and circular coats may be missing. There is no peritoneal covering unless they are situated anteriorly. If the neck is wide, no symptoms are caused, but if narrow and the diverticulum is in a dependent position, food collects in the pouch and diverticulitis may result, giving epigastric distress and tenderness. If symptoms are severe, the diverticulum may be excised, although when situated in the region of the ampulla of Vater, this may be difficult or impossible. (See also Chapter 30.)

Duodenitis

Duodenitis may occur as an isolated entity or in association with gastritis. It may be part of an inflammatory or neoplastic process of neighboring organs such as the gall bladder or pancreas. It may be the result of stasis and dilatation caused by intermittent obstruction from congenital bands or malposition. It is seldom diagnosed.

New Growths

New growths of the duodenum are extremely rare. Excluding those of the ampulla of Vater, which may arise in the common duct or the rare case of extension of a pyloric or pancreatic cancer, duodenal tumors have an incidence of a fraction of 1%. The benign tumors include adenomas (polyps), myomas, lipomas, hemangiomas, and pancreatic rests.

The pain is inconstant and not related to meals. External fistulas occasionally follow appendectomy. Abscesses may track into the pararectal space.

Diagnosis.—This is made on the symptoms, course of the disease, and the x-ray appearance. A barium enema will exclude a lesion of the large bowel such as carcinoma or diverticulitis, and a barium drink followed by x-ray will often demonstrate the narrowed, rigid ileum.

Treatment.—An expectant approach may be taken when the acute process is found at laparotomy performed on the diagnosis of appendicitis. Some cases apparently are arrested without the development of obstruction, abscesses, or fistulas. Excision of the affected portion of the bowel is the best treatment. If there is too much involvement of the mesentery, a short-circuiting operation may be done, such as an ileotransverse colostomy. The involved intestine may be removed later. Good results have been reported by Garlock by doing a short-circuiting operation and bringing the distal loop out as a mucous fistula. The prognosis must be guarded as fistulas sometimes occur after any operative procedure, toxic signs may be present after a short-circuiting operation, and recurrence may take place, even in apparently healthy bowel.

Tumors

Benign Tumors

Tumors of the small bowel are remarkably rare. The commonest benign growths are adenomas, which may be single or multiple, fibromas, which may arise in any layer; and lipomas, which may be single or multiple and may be pedunculated. Leiomyoma forms a mass projecting into the lumen of the bowel or into the peritoneal cavity. Sarcomatous changes occasionally occur in the growth. Patchy rests usually occur as small patches situated anywhere in the intestinal mucosa. They too may undergo malignant changes.

Symptoms.—The symptoms of tumors of the small intestine are usually due to complications such as obstruction, hemorrhage, or intussusception.

Treatment.—When discovered, small tumors may be removed by excision, but if this

is impossible, due to their size, resection of the involved segment of the intestine is indicated.

Malignant Tumors

Adenocarcinomas.—These may arise *de novo* or from degeneration of a benign tumor or pancreatic rest. They may cause obstruction, melena, or an annular stricture. Metastases usually occur early. The treatment is wide excision of the involved area with as much mesentery as possible. If metastases are present, the prognosis is poor. Short-circuiting procedures may be useful in relieving obstruction in cases not suitable for operation.

Sarcoma.—These develop as leiomyosarcomas, round cell sarcomas, and lymphoid tumors. They frequently grow quite large and metastasize early. The treatment in wide excision and the prognosis is bad.

Carcinoid.—These tumors arise from the argentaffine cells and occur most frequently in the submucosa of the appendix and terminal ileum. They may be single or multiple solid nodules which have a golden yellow appearance on section. They may grow to an appreciable size and cause obstruction. A certain number, which some authors place as high as 20%, metastasize to the lymph nodes and liver.

Mesenteric Lymphadenitis

Mesenteric lymphadenitis, which usually occurs in children, is characterized by attacks of crampy abdominal pain, nausea, occasional vomiting, and moderate elevation of temperature and white blood cell count. It is usually diagnosed as appendicitis. At operation the mesenteric lymph nodes are markedly enlarged, reddened, and succulent, and free fluid is often present in the peritoneal cavity. The nodes if removed at operation show only catarrhal inflammation on section, and cultures are sterile. Suppuration is rarely present. The etiology is obscure but it is probably due to a virus. It is frequently associated with lymphadenopathy elsewhere in the body. There is no evidence that it is due to trauma, tuberculosis, parasites, or enteritis.

Diagnosis.—This can usually be made on a history of attacks of colicky pain and tenderness not characteristically situated over the

appendix region. The tender area will sometimes shift to the midline when the patient lies on the left side, due to the falling of the mesentery toward the left (Klein's test).

Treatment.—The attacks tend to disappear as the child grows older. The difficulty, however, in excluding appendicitis with certainty, and the anxiety of the parents frequently leads to appendectomy. It is remarkable that many patients are completely relieved and others have fewer attacks. While mesenteric lymphadenitis is apparently a self-limited disease, appendectomy appears to have a beneficial effect on the course of the disease.

Mesenteric Vascular Occlusion Mesenteric Thrombosis

The mesenteric veins may be the site of thrombosis occurring in association with cirrhosis of the liver, following splenectomy for some blood dyscrasias, external compression from tumors, and extension of thrombophlebitic processes in the ileocolic or hemorrhoidal veins. The mesenteric arteries, usually the superior, may be occluded by an embolus arising from the mitral valve in endocarditis, the left auricle, the pulmonary veins, or arteriosclerotic plaques from one of the major vessels.

Pathology.—In *thrombosis* the bowel becomes congested, swollen, and cyanosed. There may be a temporary diarrhea due to anoxia, but the bowel soon becomes paralyzed, and gangrene is the usual outcome. However, collateral venous drainage may be established and the patient survives. In *embolism* the extent of the infarction depends on the site of the obstruction. Small areas may be saved by collateral channels, but if the superior mesenteric artery is involved, the whole small bowel and the proximal half of the colon may die. Occasionally circulation is re-established, and patients regarded as hopeless at operation have recovered.

Clinical Picture.—The condition usually appears in middle age, in a debilitated patient, following operation, or suffering from some other lesion as mentioned above. There are signs of an abdominal catastrophe, often with agonizing pain and collapse. There may be vomiting of blood and melena. Death may quickly ensue or follow soon after from obstruction or peritonitis.

Treatment.—The patient must be treated by transfusions and made ready for operation. The involved bowel must then be resected if possible. It is remarkable that many patients have survived with only a small segment of intestine remaining and have lived a reasonably normal life, so that the surgeon need not despair if huge segments of bowel have to be removed. It is possible, in cases of embolism, that the obstruction may be removed from the vessel and that circulation may be restored.

Liver and Portal Hypertension

James F. Hopkirk, M.D., Richard C. Long, M.D., et al.

THE LIVER

Anatomy

The liver is the largest glandular organ in the body and weighs normally 1,450-1,750 grams. The portal fissure is situated almost in the middle of the inferior surface, and through this enter the portal vein, hepatic artery, and the hepatic plexus of nerves. From the fissure course the hepatic veins, bile ducts, and lymphatics. The liver is covered by a fibrous sheath, Glisson's capsule, which gives rise to the intrahepatic connective tissue. Along with the vessels, the connective tissue subdivides to form the structural support for the hepatic cells segregating them into units known as the liver lobules. The hepatic lobule is the histologic unit, but the functional unit probably consists of two cords of hepatic cells with an enclosed sinusoid on one side and a bile capillary on the other.

Blood Supply—The liver receives its blood supply from two sources: the portal vein and the hepatic artery. Venous blood leaves the liver by means of the hepatic veins which have their origin in the tiny efferent veins that drain each lobule. The lobule receives blood from as many as five portal vein radicles but has only one efferent vein, which arrangement secures a more intimate contact of the blood with the hepatic cells. The portal vein carries to the liver blood which has already drained the stomach, spleen, pancreas, and the large and small intestines. During digestion and

with increase in body metabolic processes, the flow of blood in the portal system is greatly increased. Soon after entering the liver the portal vein divides into successively smaller branches, the smallest of which are found at the corners of the hepatic lobules in the interlobular spaces.

The question has been raised as to whether portal blood is essential for the normal structure and function of the liver. In animals, loss of this source of blood supply produces hepatic atrophy and deranges hepatic function. In human beings, the portal vein has been resected, with survival of the patient.

The branches of the hepatic artery accompany those of the portal vein and supply the connective tissue, the walls of the portal venules, and the bile capillaries, as well as the liver cells themselves. The amount of blood carried by the artery is about 25% of that carried by the portal system. However, the hepatic arterial blood carries an oxygen tension of 85% as compared to 30% in the portal system and is almost solely responsible for the oxygenation of the liver cells.

The hepatic and portal circulations merge via a capillary system in the interlobular spaces of the liver, and in this way mixed arterial and venous blood is supplied to the sinusoids and the liver parenchyma. The pressure differential in the two systems is equalized in the capillary bed. Within the liver lobules the blood flows between columns of liver cells in the sinusoids which are lined with undifferentiated

cells and Kupffer cells of the reticuloendothelial system

The liver lobule is a vascular unit, the exit of which is the central or hepatic vein. Each lobule is a collection of cells lying between the central vein and the portal branches with the cells radiating out from the central vein in a spokelike fashion. The cells of each column surround a lumen, the bile capillary

Normal Physiology

Effect of Hepatectomy.—Complete removal of the liver in an animal gives rise to a characteristic syndrome. For 3-8 hours the animal appears normal. Then it begins to show muscular weakness and flaccidity followed in about an hour by muscle twitching, convulsions, and death. These changes are associated with a progressive and profound fall in the blood sugar. By giving intravenous glucose it is possible to keep the animal alive for 18-30 hours. Associated with the lowered glucose curve there is a progressive drop in blood urea and an increase in amino acids, in urea acid, and in serum bilirubin levels.

Functions of the Liver

Excretory.—The liver forms and excretes about 500-1,000 ml. of bile per day at a rate of 15 ml./kilo of body weight with a secretory pressure of 200-341 mm. H₂O. The rate of flow is increased by the choleretic action of bile salts. Stimulation of the sympathetic and vagus nerves has a similar effect, although the latter also exhibits an inhibitory action. The chief components of the bile are bile pigments, the alkali salts of bile acids, organic salts, cholesterol, and mucoprotein. Its reaction is alkaline (pH 7.8-8.6).

Bilirubin.—The formation of bilirubin takes place in the reticuloendothelial system throughout the body from the breakdown of hemoglobin and probably myoglobin and the respiratory enzyme cytochrome-C. It is then excreted by the parenchymal liver cells. The cells alter the bilirubin to some extent as shown by the direct and indirect van den Bergh reaction. The bile pigment has no useful function and is purely an excretory product. Once formed in the reticuloendothelial system the bilirubin is absorbed onto protein fractions in the blood

serum which prevents its excretion by the kidney. This tie is broken by the liver cells, and free bilirubin is excreted in the bile. In the bowel the reducing action of *Escherichia coli* changes it to urobilinogen.

Bile Salts.—The bile salts are a specific secretion of the liver. All are derivatives of cholane, a polycyclic hydrocarbon, which is conjugated in the liver cells with the amino acids, glycine and taurine, to form glycocholic and taurocholic acids. Bile salts have a number of functions; e.g., they aid the digestion of fat by emulsification; the stimulation of the production of pancreatic enzymes, amylase, trypsin, and especially lipase; the absorption of fat soluble vitamins A, D, E, and K. They also help to keep the cholesterol of the bile in solution.

Metabolic.

Carbohydrate.—The liver stores carbohydrate in the form of glycogen and also supplies glucose to the body as it is needed by converting its glycogen reserve. It can also manufacture glucose from protein and to a lesser extent from fat. The entire activity of the liver in carbohydrate metabolism is designed to maintain a normal blood sugar.

Protein and Nitrogen Metabolism.—The liver stores protein, and it manufactures albumin, fibrinogen, prothrombin, and a portion of the globulin fraction. It is the site of urea formation as the end product of the deamination of protein.

Fat Metabolism.—Varying amounts of fat are stored in the liver, depending upon the nutritional state of the individual. The liver also desaturates fatty acids and manufactures ketone bodies which are catabolized by the tissues. Cholesterol is combined with fatty acids in the liver to form cholesterol esters, and this is one of the media for the transportation of fat.

Water Metabolism.—The liver acts as a storage organ for water and as a reservoir for blood and so assists in the regulation of the blood volume.

Vitamin Metabolism.—It manufactures vitamin A from carotene and stores it. It also stores vitamin B and can convert vitamin K to prothrombin.

Pigment and Porphyrin Metabolism.—The liver excretes porphyrins and reconverts some urobilinogen to bilirubin.

Blood Formation.—In the embryo the liver is one of the sites of red blood cell formation. In adults it serves as storage center for the antipernicious anemia factor and for copper and iron.

Blood Coagulation.—It is the site of formation of fibrinogen and prothrombin.

Ammonia Metabolism.—There are three sources of ammonia:

1 From absorption from the gastrointestinal tract of the ammonia derived from proteolytic enzymes and bacteria acting on ingested food.

2 From the functional activity of the kidney, converting glutamin in ammonia and glutamic acid by a special renal enzyme, *glutaminase*. Most of the ammonia is excreted in the urine but some passes back into the circulation.

3 From deamination in protein metabolism. Ammonia is eliminated as urea and uric acid after their synthesis in the liver. High blood ammonia levels are important to the surgeon as they are found in (a) patients who have undergone shunting procedures to ameliorate portal hypertension, and (b) those who have chronic liver disease associated with a gastrointestinal hemorrhage.

INJURIES TO THE LIVER

Etiology.—Injury may occur as the result of blunt trauma to the right upper abdomen or lower thorax, from penetrating wounds, or from operative trauma.

Pathology.—The right lobe is usually involved. The degree of damage varies from simple contusion to subcapsular or even complete rupture. Associated injury of the abdominal and thoracic viscera commonly occurs.

Clinical Picture.—In the absence of an external wound, there may be some difficulty in making the diagnosis. Abdominal pain with tenderness in the right hypochondrium is characteristic. If the tear is large, signs of hemorrhagic shock may appear, and dullness in the flanks may result from the blood in the peritoneal cavity. An x-ray of the chest and abdomen should always be taken to help rule out injury to other viscera.

Treatment.—In the absence of injury to other abdominal viscera, the treatment should be conservative. Whole blood transfusions may be necessary to restore the blood volume and overcome shock. Uncontrolled hemorrhage requires laparotomy and suture of the liver tear.

INFECTIONS OF THE LIVER

Liver Abscess

Etiology.—Abscesses develop from infection which reaches the liver from the systemic circulation in general pyemia, from the portal vein in septic thrombophlebitis, from the bile duct in acute cholangitis, or from a neighboring focus by direct spread.

Pyemic Abscess

Etiology.—In any case of general pyemia, multiple septic emboli are set free, some of which reach the liver via the hepatic artery, causing numerous small abscesses. These are seldom suspected during life unless jaundice occurs. The treatment is that of the general systemic infection.

Pylephlebitic Abscess

Etiology.—Any suppurative process within the abdomen may cause a septic thrombophlebitis in the portal vein. The appendix is the commonest site of origin. The infected thrombus extends along the vein to the liver, or emboli are set free, which are carried to the liver by the portal system.

Pathology.—The abscesses are usually multiple, vary greatly in size, and are more common in the right lobe. If the abscess is situated close to the surface of the liver, it may rupture into the peritoneal or pleural cavity.

Clinical Features.—The antecedent suppurative process is followed after an interval by the secondary development of septicemia with severe chills and fever. Eventually hepatic involvement occurs with right upper quadrant pain, an enlarged tender liver, and jaundice. If the splenic vein is involved, splenomegaly may occur.

Signs of intrathoracic disease indicated by a raised right diaphragm on x-ray examination and signs of pleural involvement are common.

Treatment.—The early treatment of intra-abdominal suppuration by adequate surgery

and appropriate antibiotic therapy will usually prevent pylephlebitis. If the laparotomy reveals evidence of thrombosis of the portal system, the involved veins may be ligated to prevent proximal spread, and a course of anticoagulant therapy should be given.

If liver abscesses develop, they should be drained preferably by an extraperitoneal approach. Anticoagulants and antibiotic therapy should be given in maximum dosage.

Cholangitic Abscess

These abscesses form secondary to acute suppurative cholangitis and hence occur along the intrahepatic bile ducts. The clinical picture is one of intermittent fever, chills, jaundice, and a tender enlarged liver.

The treatment is drainage of the common duct and antibiotic therapy. If any large abscesses are present, they should be drained extraperitoneally.

Amebic Abscess

Etiology.—The *Entamoeba histolytica*, found in many parts of the world, may cause a hepatitis which in some cases goes on to abscess formation.

Pathology.—Amebic abscesses are usually solitary and occur or develop in the right lobe of the liver. The amebae reach the liver via the portal circulation from the primary intestinal ulcers.

The abscess is formed by liquefaction of an area of hepatitis by a proteolytic toxin produced by the amebae. The abscess is typically sterile, and only by scraping the wall can amebae be demonstrated.

Clinical Picture.—An abscess may develop at any stage of the disease. The symptoms are fever, profuse sweating, weakness, and marked gastrointestinal upset. There is pain in the right upper quadrant and an enlarged tender liver. X-ray shows an elevation and immobilization of the right diaphragm. The presence of the *E. histolytica* in the stool confirms the diagnosis.

Treatment.—Emetine and chloroquine have been used in the treatment of the intestinal ulceration and hepatitis. When abscesses form, drainage of the abscess is essential, taking every precaution to maintain the sterility of

the abscess. This drainage may best be done by aspiration at laparotomy.

Actinomycosis

Actinomycosis of the liver is very rare and develops from a focus of infection in the abdomen or thorax (most commonly in the ileocecal region).

Pathology.—The liver is enlarged and adherent to surrounding structures. It is pitted with numerous small abscesses, giving it a honey-combed appearance. The disease may invade the abdominal wall with resulting sinus formation.

Clinical Picture.—The initial symptoms are those of the primary disease. Upper abdominal pain, fever, and an enlarged tender liver are signs of hepatic involvement.

Treatment.—Antibiotic therapy will arrest the disease in many instances. (See Bacteriology, p. 65.) If the abscess is accessible, it should be drained and the necrotic tissue excised.

CYSTS OF THE LIVER

Retention Cysts

Retention cysts are small single cysts, lined with a flattened epithelium, and are thought to be due to a malformation of the smaller bile ducts. They are usually asymptomatic unless large enough to press upon surrounding structures.

Treatment.—The cyst should be excised if symptoms develop.

Polycystic Disease

Polycystic disease frequently occurs in association with polycystic kidneys. The cysts are multiple, vary greatly in size, and contain a clear albuminous fluid.

Treatment.—Treatment is usually unsatisfactory because of the wide distribution of the cysts in the liver and in other organs.

Parasitic Cysts (Hydatid Disease)

Etiology.—The *Taenia echinococcus* is ingested by man in food contaminated by the excreta of dogs and other canines. The embryos penetrate the intestinal wall and are carried to the liver by the portal vein. The

great majority of the embryos are arrested in the liver but may pass through into the systemic circulation and lodge in the lungs or other organs.

Pathology.—When the embryo reaches the liver, it becomes encysted and the cyst gradually increases in size. The fully developed cyst has two layers, an outer laminated fibrous layer and an inner germinal layer from whose cells grow daughter cysts. The parent cyst is usually solitary and contains a clear gelatinous material in which are imbedded many daughter or granddaughter cysts.

Clinical Picture.—When the cysts are small, they are asymptomatic; but as the disease progresses, the cysts enlarge and symptoms develop. Dull pain in the right hypochondrium is common and jaundice may occur. Physical examination will usually reveal a palpable mass on the surface of the liver.

Urticaria, eosinophilia, and other manifestations of the developing allergic phenomena are seen. As calcification of the cyst wall is common, a plain film of the abdomen may be of help in the diagnosis.

There are two confirmatory tests:

1. The Casoni reaction—the intradermal injection of the fresh fluid from animal hydatid cysts.

2. The Chedini-Weinberg complement-fixation reaction.

The cysts may rupture into (1) the peritoneal cavity, (2) the pleural cavity, lung, or bronchus, with the development of a bronchobiliary fistula, or (3) the gastrointestinal tract.

Treatment.—Operation is the treatment of choice. Careful localization of the cyst is essential in order that the incision may be placed correctly. When the cyst is exposed and carefully packed off, it is aspirated and the contents are replaced by a solution of 10% formalin. The cyst is opened and the inner layers are carefully excised. The cavity is closed and the abdomen is sutured without drainage. Partial hepatectomy may be required if the cysts are multiple.

TUMORS OF THE LIVER

Benign.—Adenoma, lymphangioma, hemangioma, myoma, teratoma, fibroma.

Malignant.—(1) Primary carcinoma (hepatoma, cholangioma), sarcoma; (2) secondary.

Benign Tumors

Benign tumors are an uncommon cause of symptoms although they are frequently found at operation and post mortem. Adenomas and hemangiomas may become large enough to present as a mass in the upper abdomen or may press upon neighboring viscera to cause symptoms.

The treatment of these tumors should be excision if possible.

Malignant Tumors

Primary Carcinoma

Primary carcinoma of the liver is a rare disease. It arises from either the liver cells (hepatoma) or from the cells of bile ducts (cholangioma). The *hepatoma* is commoner in the male and is frequently preceded by portal cirrhosis. The *cholangioma* is commoner in females, and this fact may have some relationship to the greater incidence of gall bladder disease in this sex.

Pathology.—The tumor may take the form of multiple nodules, a single large mass, or a diffusely infiltrating growth. In hepatoma the cells are arranged in cords or solid alveoli, and contain bile pigment. Cholangiomas consist of closely packed tubules with a highly vascular stroma. Metastases to other organs are rare.

Clinical Picture.—The onset is insidious with anorexia, loss of weight, and anemia. An enlarged liver, emaciation, ascites, and perhaps jaundice make the diagnosis more obvious. The disease runs a rapid and downhill course with death occurring within 3-4 months after the onset of symptoms. Liver biopsy is necessary to establish a correct pathologic diagnosis.

Treatment.—In the diffuse form or where multiple nodules are present, nothing can be done. Rarely, when a solitary primary tumor is found, resection of a part or all of a lobe may be undertaken. X-ray therapy is without effect.

Primary Sarcoma

Primary sarcoma is an extremely rare lesion. The treatment is one of palliation, although some temporary relief may be expected from x-ray therapy.

Secondary Carcinoma

Secondary carcinoma of the liver is very common in patients with malignant disease. The primary growth may lie in any part of the gastrointestinal tract drained by the portal vein; it may arise elsewhere in the body, e.g., uterus, bronchus, breast, and reach the liver by the systemic circulation; or it may invade the liver by direct extension or by the lymphatics.

The metastases are nearly always multiple. The liver progressively enlarges and presents a nodular surface. Pain, jaundice, and ascites eventually occur.

Treatment.—Treatment should be directed toward the alleviation of symptoms. However, in the rare case where the primary growth has been adequately excised and a solitary metastasis develops in the liver, resection of the involved lobe may be advisable.

SURGICAL JAUNDICE

Jaundice is a manifestation of an increase in the bilirubin level of the blood which gives a yellow discoloration of the skin, sclerae, and mucous membranes. The hyperbilirubinemia results from a number of diverse mechanisms, not all of which are associated with the liver and biliary system.

Pathogenesis of Jaundice.—When the red blood cell is broken down, it divides into an iron-free molecule and an iron-containing portion (hemosiderin). It is the iron-free molecule which is the precursor of bilirubin. The cells of the reticuloendothelial system convert this molecule to bilirubin-globin, which is removed from the blood stream by the liver and is excreted as sodium bilirubinate by the liver cells as one of the components of the bile. In the gastrointestinal tract the bilirubin is acted upon by bacteria and is reduced to urobilinogen, most of which is excreted in the stool. The remainder is reabsorbed and carried by the portal circulation to the liver. Here the greater part is converted to bilirubin, but some reaches the systemic circulation and is excreted in the urine. The unabsorbed urobilinogen in the bowel is oxidized to urobilin which is partly responsible for the color of normal stools.

Jaundice is due either to an increased rate of bilirubin production or to a decrease in the rate of its excretion. An increased rate of production may be due to:

1. Increased susceptibility of the red blood cells to hemolysis, e.g., congenital hemolytic jaundice

2. Presence of hemolysin, e.g., incompatible blood transfusions

3. An overactive reticuloendothelial system. A decreased rate of excretion may be due to:

1. Damage to liver parenchymal cells
 - a. In infections, e.g., infectious hepatitis
 - b. Toxic agents, e.g., phosphorus, arsenic
 - c. In cirrhosis

2. Obstruction to the flow of bile which is usually extrahepatic, e.g., stone or tumor

Classification of Jaundice.—There are three main types; however, it is difficult to differentiate these exactly, as there is frequently an overlap of one type with another.

1. Hemolytic due to the excessive production of bilirubin from the destruction of large numbers of erythrocytes, e.g., congenital hemolytic jaundice

2. Hepatocellular due to a disturbance in the liver cells from
 - a. Infections due to virus infection, e.g., leptospiral infection, syphilis, etc.
 - b. Chemical poisons: alcohol, arsenic, chloroform, carbon tetrachloride
 - c. Biologic substances: incompatible blood
 - d. Miscellaneous: portal cirrhosis

3. Obstructive due to some obstruction of the flow of bile
 - a. Within the lumen of the bile duct: e.g., stone, inflammatory exudate, parasites
 - b. Changes in the wall of the duct: stricture, inflammation, neoplasm, or spasm of the sphincter of Oddi
 - c. Pressure on the ducts from within: pancreatic lesions; hepatic lesions; enlarged glands at portal fissure, duodenal and gastric lesions

4. Mixed: When the initial lesion, e.g., obstruction, is followed by secondary changes in the liver cells which contribute to the duration and severity of the jaundice

The Problem of Diagnosis.—There are many causes of jaundice, but there are only four which commonly confront the surgeon

1. Stone in the common duct
2. Carcinoma of the pancreas
3. Infectious hepatitis
4. Hemolytic jaundice

The differential diagnosis of jaundice presents great difficulty. Much can be learned from an accurate history, but certain laboratory procedures are an essential aid in ascertaining the etiology.

In jaundice due to common duct stone, there frequently is a history of biliary dyspepsia which may be associated with one or

more attacks of biliary colic. The onset of the jaundice is commonly preceded by such an attack. Because the obstructive factor can be intermittent, the depth of the jaundice fluctuates. Slight variation in its depth usually is not detectable clinically, and repeated estimation of the serum bilirubin must be made. The icterus is usually accompanied by pruritus due to the deposition of bile salts in the skin. The latter symptom does not occur in the nonobstructive types of jaundice. Physical examination is of little help although there may be

Fig 295—Diagrammatic representation of normal and abnormal bile metabolism. The size of the arrows shows in an approximate fashion the magnitude of abnormal bile or bile product flow.

tenderness over the gall bladder area during the acute attack. The stools are clay-colored at the height of the jaundice but vary in color with the fluctuation in the degree of icterus. The urine is strongly bile-colored, and this is one of the earliest signs of jaundice.

The *jaundice due to malignant obstruction of the common duct* develops slowly and progressively and is not typically associated with attacks of biliary colic, although dull upper abdominal pain is frequent. There are commonly symptoms of anorexia, loss of weight, and a general lack of well-being. If the obstruction is distal to the entrance of the cystic duct, the undiseased gall bladder becomes distended with bile and may be palpable (Courvoisier's law). Occasionally, the jaundice fluctuates due to ulceration of the tumor or to a ball valve action of a pedunculated neoplasm. As in the jaundice of common duct stone, the stools are clay-colored, the urine is strongly stained with bile, and pruritus is a frequent symptom. Small amounts of occult blood may be present in the stools.

The *jaundice of infectious hepatitis* is preceded by a period of anorexia, nausea, and vomiting and is not associated with severe pain. Enlargement of the liver causes a dull ache in the right upper quadrant due to stretching of the liver capsule. The jaundice deepens rapidly, usually lasts for 3-4 weeks, and then gradually disappears. During this period the stools are clay-colored and the urine bile-stained. The liver is enlarged and tender unless yellow atrophy supervenes. Pruritus is absent.

Hemolytic jaundice is due to an excessive destruction of red blood cells. It is characterized by an elevation in the serum bilirubin and the urobilinogen content of the stool and urine. (See Chapter 22, Spleen.)

Liver Function Studies

No single test has been found that will measure liver function accurately, and it is therefore necessary to employ a group of procedures, each of which measures a different aspect of liver physiology. If obstructive jaundice is of long standing, liver function studies are unreliable because of the secondary hepatocellular damage. Once the diagnosis has been established, these tests may be utilized to follow the progress of the disease.

Classification

1. Tests based upon the metabolism of bile pigments
 - a. Quantitative serum bilirubin (van den Bergh)
 - b. Urobilinogen content of urine and feces
2. Tests based upon the excretory function of the liver
 - a. Bromsulphalein
3. Tests based upon the activity of the liver in protein metabolism
 - a. Serum protein: total, albumin, and globulin
 - b. Blood prothrombin time and its response to vitamin K
 - c. Cephalin-cholesterol flocculation test
 - d. Thymol turbidity and thymol flocculation
4. Tests based on the activity of the liver lipid metabolism
 - a. Total cholesterol level of the blood
 - b. Ratio of total cholesterol to cholesterol esters
5. Tests based upon the detoxifying function of the liver
 - a. Hippuric acid synthesis
6. Miscellaneous
 - a. Alkaline phosphatase level

Quantitative Serum Bilirubin.—(Normal: 0.1-0.8 mg/100 ml.) Jaundice is best measured by the quantitative estimation of the serum bilirubin. A slight degree of hyperbilirubinemia may not cause visible discoloration of the tissues. However, jaundice becomes clinically evident when the serum bilirubin level reaches 2.5-3.0 mg/100 ml. The total bilirubin is made up of two fractions, the direct and the indirect. The *indirect van den Bergh* is the measure of bilirubin before it has passed through the liver cells (bilirubin-globin). It is so called because it is chemically inactive and will not combine with the reagent (Ehrlich's diazo reagent) without the addition of a substance which lowers its surface tension. Once it has passed through the liver cells, it is changed to sodium bilirubinate which readily reacts with the reagent and gives the *direct reaction*. Normally 40-75% of the total bilirubin is of the direct variety. An *indirect reaction* is found in cases of hemolytic jaundice.

TABLE 20
URINE AND STOOL BILE AND UROBILINOGEN LEVELS IN JAUNDICED PATIENTS

	URINE		FECES
	BILE	UROBILINOGEN	UROBILINOGEN
Normal	0	+	+
Hemolytic jaundice	0	+++	++
Hepatocellular jaundice	+	0	+ or ++
Obstructive jaundice	++	0	II

TABLE 21
LIVER FUNCTION TEST VALUES IN JAUNDICE

	NORMAL VALUES	HEMOLYTIC JAUNDICE	OBSTRUCTIVE JAUNDICE	HEPATOCELLULAR JAUNDICE
Serum protein	6.9-8.5 Gm./100 ml	Normal	Normal	Decreased
A/G ratio	3:1	Normal	Normal	Reversed
Prothrombin	100%	Normal	Decreased	Decreased
Cephalin-cholesterol	0-1+	Normal	Normal or 2 plus	2 or more plus
Thymol turbidity	< 4 units	Normal	Normal	Increased
Thymol flocculation	0-1+	Normal	0-1 plus	Over 1 plus
Cholesterol total	150-250 mg./100 ml	Normal	Increased	Decreased
Cholesterol esters	75-175 mg./100 ml	Normal	Increased	Decreased
Hippuric acid synthesis	> 1 Gm	Normal	Normal	Decreased
Alkaline phosphatase	3-13 units	Normal	Increased	Normal

while a direct reaction is found in both obstructive and hepatocellular jaundice.

Urobilinogen Content of Urine and Feces—(Normal Urine, 0.3-5 mg./day. Feces, 40-280 mg./day) The estimation of the urobilinogen content of the urine and stools is of great value in the differential diagnosis of jaundice and in evaluating the progress of the disease. In complete obstructive jaundice, where no bilirubin reaches the intestine, urobilinogen will be absent from both the feces and the urine. The stools are clay-colored. In hepatocellular jaundice the ability of the liver to re-excrete the urobilinogen is impaired, the blood level rises, and the amount excreted in the urine is increased. In hemolytic jaundice, with consequent increase in erythrocyte destruction and thus an increased bilirubin formation, the level of the urobilinogen in stool and urine is markedly increased.

Bromsulphalein Test.—(Normal. 95% of dye excreted in 30 minutes) The liver has the capacity to remove certain dyes from the circulation and excrete them in the bile. Liver disease prevents this excretion, and a high percentage of the dye may be retained. As this is a colorimetric test, it is invalidated in the presence of jaundice, and because of the added burden placed upon the liver, its use

for patients suspected of having obstructive jaundice is contraindicated. Its chief value lies in the assessment of liver function in the patients without jaundice. This test is performed by an intravenous injection of 5 mg. Bromsulphalein per kilogram of body weight.

Serum Protein.—(Normal: total 6.9-8.5 Gm./100 ml.; albumin 4.4-6.0 Gm./100 ml.; globulin 1.5-3.0 Gm./100 ml.)

Albumin, globulin, fibrinogen, and prothrombin are formed in the liver. Changes in the metabolism of these protein fractions occur in liver disease. In advanced liver disease a marked decrease occurs in the total serum proteins, and this is chiefly, if not entirely, in the albumin fraction. Occasionally there may be a rise in the serum globulin level which leads to a reversal of the normal albumin-globulin ratio and may even result in an increase in the level of the total serum protein level.

Prothrombin.—Prothrombin is formed by the liver in the presence of an adequate supply of vitamin K. Two factors are therefore necessary for its production—adequate intake and absorption of vitamin K, and a functioning liver. In simple obstructive jaundice the exclusion of bile salts from the intestine and the consequent lack of absorption of the fat-soluble vitamin K result in a decreased forma-

tion of prothrombin. In such cases parenteral administration of vitamin K will bring the prothrombin concentration to normal. In severe hepatocellular damage there is also a decreased prothrombin formation, but this is refractory to the administration of vitamin K. This failure to respond occurs only in the presence of severe liver damage.

Cephalin-Cholesterol Flocculation Test.—In hepatocellular damage, gamma globulin is produced in increased amount, while serum albumin formation is decreased. This change in the serum proteins causes a flocculation of a cephalin-cholesterol emulsion. This test is unaffected by jaundice and is a very sensitive test of hepatic function. Its chief value lies in differentiating obstructive from hepatocellular jaundice. In hepatocellular jaundice strongly positive reactions (3 or 4 plus) are the rule. In liver damage due to long-standing biliary obstruction, the test is positive, but not usually more than 1 or 2 plus.

Thymol Turbidity Test and Thymol Flocculation Test.—(Normal: turbidity, less than 4 units; flocculation 0-1 plus.) This is a flocculation test similar to the cephalin-cholesterol test but is considerably less sensitive. It too is unaffected by the presence of jaundice. In jaundice due to extrahepatic biliary obstruction, the values are within normal limits. In hepatocellular jaundice the values are elevated. The thymol flocculation test is a continuation of the thymol turbidity procedure and in the absence of jaundice is much more sensitive.

Plasma Cholesterol and Cholesterol Esters.—(Normal: total cholesterol 150-250 mg/100 ml, cholesterol esters, 75-175 mg/100 ml.) Hypercholesterolemia commonly occurs in obstructive jaundice, and the ratio of total cholesterol to cholesterol esters is normal. In very severe hepatocellular damage, lowered values frequently occur, and the proportion of cholesterol esters is diminished.

Hippuric Acid Synthesis.—(Normal: over 1 Gm.) Benzoic acid is conjugated in the liver with glycine to form hippuric acid which is excreted in the urine. The amount excreted is subnormal in patients with hepatocellular jaundice but is normal in uncomplicated obstruc-

tion to the common duct. The renal function must be normal if this test is to be accurate.

Alkaline Phosphatase.—(Normal: 3-13 units [King-Armstrong].) Alkaline phosphatase is an enzyme produced by the osteoblasts at the site of bone formation. It is excreted by the liver in the bile. In obstructive jaundice the alkaline phosphatase is markedly increased but is normal or very slightly elevated in hepatocellular jaundice.

Liver Biopsy

In combination with liver function studies, a liver biopsy may assist materially in establishing the cause of jaundice. This may be done by aspiration needle biopsy or under direct vision at the time of laparotomy. This diagnostic procedure carries with it the risk of fatality, usually due to intra-abdominal bleeding. The onset of hemorrhage may be delayed for some hours or even days. Bile peritonitis, infection, and pneumothorax are rare complications. To be of value, a representative piece of liver must be obtained, and this is not always possible in a single aspiration. The famular laboratory cork borer is a useful biopsy instrument.

PORTAL HYPERTENSION

Portal hypertension is a manifestation of a variety of disease processes having in common obstruction to the portal circulation, either within or without the liver (see also Chapter 30).

McMichael (1931) introduced the term *portal hypertension* and suggested that such a derangement might occur in the absence of cirrhosis. This concept was further developed by Whipple and Rousselot (1937), who demonstrated by manometric measurements greatly increased pressure in various portal tributaries in many patients presenting congestive splenomegaly, in whom the liver appeared normal when examined at laparotomy.

The surgical significance of portal hypertension is based on the fact that repeated and ultimately fatal hemorrhages from esophageal or gastric varices may complicate the course of this disorder. To circumvent this eventuality, attempts were made to create an adequate by-

pass or shunt between a major portal tributary and a systemic vein. This was achieved in 1943 by Whipple and his colleagues, and since that time increased interest and experience have made such a surgical procedure an accepted form of treatment in carefully selected cases.

Pathogenesis.—The obstruction of the portal system may be either *congenital* or *acquired*, and the sites of the obstructive factor may be either *intrahepatic* or *extrahepatic*.

In the majority of cases of *intrahepatic* block this is due to cirrhosis.

The *extrahepatic* block follows thrombosis of the portal, superior mesenteric, or splenic vein, which is usually due to *pylephlebitis* sub-

sequent to an inflammatory lesion in the alimentary tract or omphalitis in the newborn child.

Rousselot has divided the obstructions into two major groups, *intrahepatic* and *extrahepatic*, as follows.

1. *Intrahepatic*

a. Cirrhosis of the liver

- (1) Laennec's cirrhosis
- (2) Schistosomiasis
- (3) Biliary cirrhosis
- (4) Infectious hepatitis

2. *Extrahepatic*

a. Stenosis of vein

- (1) Congenital
- (2) Acquired (phleboscлерosis)

Fig 296—Sites of obstruction causing increased hydrostatic pressure in the portal venous bed

- A, Obstruction of the splenic vein distal to the entrance of the inferior mesenteric vein
- B, Obstruction of the splenic vein proximal to the entrance of the inferior mesenteric and coronary veins
- C, Obstruction of the portal vein
- D, Intrahepatic obstruction due to cirrhosis of the liver

LIVER AND PORTAL HYPERTENSION

- b Compression of vein
 (1) Inflammatory (e.g., pancreatitis)
 (2) Pancreatic cyst
 (3) Tumor
 (4) Aneurysm of splenic artery
- c Thrombosis of vein
 (1) Inflammatory
 (2) Traumatic
- d. Cavernomatous transformation of vein (portal)

The Liver Circulation in Cirrhosis.—Associated with the widespread fibrosis there is a marked distortion of the portal and hepatic

different stages of the disease. It has recently been shown (Madden, 1954) that in cirrhosis with irreversible ascites there is an increase in the arterial and the portal beds and a decrease in the hepatic venous bed. In cirrhosis without ascites or in those cases where the ascites is reversible, the entire vascular bed is decreased.

Clinical Picture.—The principal clinical manifestations of portal hypertension are splenomegaly and the development of collaterals between the portal and systemic veins. These develop characteristically in the esophagus where they give rise to esophageal varices;

Fig 297.—Pressures in the various components of the hepatic circulation and the amount of blood contributed by each component (After Ravdin, I S. Ann Roy. Coll Surgeons England 20: 71-98, 1957)

veins, and consequently the liver becomes increasingly dependent upon the hepatic artery as a source of its blood supply. As a result, extensive shunts develop between the branches of the hepatic artery and the portal vein and also between the branches of the portal and hepatic veins. The intrahepatic shunts divert a large portion of the portal blood flow past the liver cells. These shunts in combination with the extrahepatic venous shunts form multiple internal and external Eck fistulas. This phenomenon is not static, varying with

at the anus with the development of hemorrhoids, and in the abdominal sites where the abdominal contents become retroperitoneal developmentally or adherent to the abdominal wall as the result of a pathologic process. It should be realized, however, that portal hypertension may exist without the development of esophageal varices, although other collateral channels may exist. There is an associated anemia, leukopenia, and thrombocytopenia, probably due to hyperfunction of the spleen, i.e., hypersplenism.

Fig 298A—Normal portal venous system which can be partially visualized by x-ray examination after intrasplenic injection of a radiopaque substance such as Diodrast. In cases of portal hypertension, anastomotic channels, esophageal varices, and abnormalities in the portal and splenic veins can be demonstrated.

Fig 298B—Splenoportogram demonstrating intrahepatic obstruction. *a*, Dye injected by needle into splenic pulp. *b*, Tortuous splenic vein. *c*, Markedly dilated coronary vein. *d*, Gross esophageal varices. *e*, Portal vein.

If the block is *intrahepatic* the liver is usually shrunken and its tests of function abnormal. Total serum proteins are decreased and the albumin-globulin ratio may be reversed. Ascites, swollen legs, and the other manifestations of cirrhosis such as palmar erythema and gynecomastia are usually apparent.

If *extrahepatic* the liver is normal except in the rare instances of purely coincidental cirrhosis.

The presence of esophageal varices can be confirmed by radiologic examination and by esophagoscopy. The dilated anal veins are readily seen on proctoscopic examination. It is interesting that in most cases one or another

Surgical Treatment.—The surgical treatment is primarily directed toward the arrest of hemorrhage and the prevention of its recurrence by measures which reduce the portal pressure or obliterate esophageal varices. Splenectomy will also correct the hematologic manifestations of hypersplenism.

In the intrahepatic type, the selection of patients for operative treatment should be carefully made, as in this group the results of surgery are not as satisfactory as for those of the extrahepatic variety. Severe impairment of liver function as revealed by ascites, jaundice, hepatic coma, or a serum albumin below 3 Gm. % are usually contraindications. However,

Fig. 299—Standard shunting operations for the relief of portal hypertension
 A, Where the obstruction is in the portal vein, splenectomy with end to side anastomosis of the splenic to the left renal vein is carried out
 B, Anastomosis, side-to-side, of the portal vein and inferior vena cava, in the presence of intrahepatic portal obstruction

of these collateral sites is involved, not necessarily both. The site of the obstruction can often be determined by the use of *portal venography*. This test is of considerable value, therefore, in indicating which of the shunt procedures should be carried out. It is accomplished by the intrasplenic injection of a contrast medium such as Diodrast, with immediate serial x-ray exposures, performed immediately prior to operation because of the danger of serious hemorrhage from the spleen. This gives an outline of the splenic and portal veins with the normal and abnormal anastomotic vessels.

many cirrhotics who bleed can be improved by medical management to the point where they are suitable for surgery. All patients with esophageal varices do not present with hemorrhage, although it can be assumed that if they live long enough bleeding will eventually occur. The immediate cause of the hemorrhage is acid peptic ulceration of the thin-walled varices as a result of an incompetent cardiac sphincter with reflux of the gastric contents. The following procedures may be used:

- 1 To control hemorrhage:
 - a Emergency intra-esophageal tamponade using Sengstaken-Blakemore balloon

Plate 25.—Esophageal Varices.

The x-ray clearly demonstrates irregular filling defects caused by distended veins in the lower third of this esophagus. The varicose condition, however, commonly extends to the level of the aortic arch or even higher

b. Obliteration of the esophageal varices by direct suture

c. Resection of the lower end of the esophagus and cardiac end of the stomach

2. To reduce the portal pressure:

a. Portacaval anastomosis, either end-to-side or side-to-side (Tck fistula)

b. Splenorenal anastomosis with removal of the spleen and end-to-side anastomosis of the splenic to the left renal vein; left kidney preserved

c. Splenectomy; only of value if the obstruction is situated in the splenic vein between the spleen and the entrance of the inferior mesenteric vein

In order to select the correct shunt procedure it is essential that the surgeon determine the pressure in the different radicles of the portal system. This is done by the insertion of a needle with an attached manometer at the time of laparotomy. The normal pressure is 12-16 cm. of saline, and this may be raised in cases of portal hypertension to 50-60 cm. of saline

If the pressure is elevated in the splenic vein but normal in the superior mesenteric vein, the block is limited to the splenic vein, and the portal vein is clear. If pressures are increased in all radicles of the portal system, then the block is intrahepatic or in the portal vein adjacent to the liver.

At the present time the consensus is that the best procedure in cases of intrahepatic block is portacaval anastomosis. In cases due to an extrahepatic block, this procedure is rarely feasible, and splenorenal anastomosis must be performed. The study of the preoperative portogram is of great assistance in deciding the type of anastomosis for the case in question. Experience has shown that if the establishment of a venous shunt is successful in reducing the portal pressure to a level below 30 cm. of saline, recurrence of serious hemorrhage from esophageal varices is a rare event. It should be realized, however, that the course of associated disease processes such as cirrhosis of the liver is not affected by the operation.

ACUTE HEPATIC FAILURE

Failure of the cellular function of the liver can occur in almost any form of liver disease.

It is found most commonly (1) following operation on the patient with viral hepatitis, (2) in patients with portal cirrhosis with bleeding esophageal varices, and (3) following accidental ligation of the hepatic artery.

Clinical Features.—Hepatic failure is characterized clinically by the development of jaundice, fever, ascites, and neurologic changes (coma).

Hepatic coma is commonly associated with esophageal bleeding in patients with cirrhosis. The symptoms are associated with an increase in blood ammonia secondary to its increased production in the gastrointestinal tract, from the breakdown of the blood protein. This ammonia by-passes the liver, where it is normally detoxified, and causes a functional abnormality in the brain.

Such patients are confused, may have hallucinations, or be frankly comatose and show a characteristic flapping tremor. There may be clonus, an extensor plantar response, convulsions, and sometimes death.

Treatment.—The principle of treatment is the reduction of the protein in the gastrointestinal tract by (1) control of the hemorrhage, (2) removal of the accumulated blood by catharsis, (3) restriction of protein intake, (4) use of antibiotics to diminish the activity of intestinal bacteria which produce ammonia, and (5) the administration of glutamic acid which combines with ammonia to form glutamine.

The prognosis in these cases should be guarded. The process is reversible, and recovery can occur even from severe coma, particularly if the precipitating factor can be removed.

ASCITES

Ascites is an accumulation of fluid in the peritoneal cavity. The commonest causes, in the absence of some local etiologic factor (e.g., carcinomatosis), are cirrhosis and cardiac failure.

Pathogenesis.—The development of ascites is dependent upon a number of factors.

1. Decrease in the serum osmotic pressure due to a lowering of the serum albumin.

2. Retention of the sodium ion. There is almost complete absence of urinary sodium in

REFERENCES

patients with cirrhosis and ascites. Although the serum sodium concentration may be low in these patients, relatively large quantities of salt may be held in the extravascular fluid compartments. The mechanism of this retention is not completely clear, but it is probably due to increased renal tubular absorption, possibly to an antidiuretic hormone, and may also be due to adrenocortical activity.

3. Obstruction to the hepatic venous outflow. This obstruction may be due to obliterative fibrosis of the veins in those patients with irreversible ascites, or to intrahepatic cellular edema in those patients with reversible ascites from either cirrhosis or cardiac failure. In malignancy there may be blockage of these veins by tumor.

Treatment.—Primarily, the treatment of ascites is medical, i.e., the restriction of sodium intake, the administration of ionic exchange resins, and a diet high in protein, carbohydrate, and vitamins. Intravenous serum albumin is of limited value, as it rapidly goes into equilibrium with the albumin of the ascitic fluid. The surgical treatment at the present time is unsatisfactory. There are two promising avenues of approach: (1) the establishment of an isolated segment of ileum with the mucosa exposed to the peritoneal cavity, which effectively absorbs the ascitic fluid, and (2) the establishment of a collateral circulation or shunt to bridge the blocked outflow tract. The use of extrahepatic portacaval shunts and ligation of the hepatic artery will at times prevent the accumulation of ascitic fluid.

Chapter 20

Biliary System

James F. Hopkirk, MD, and Richard C Long, MD

ANATOMY

The hepatic duct is formed in the depth of the transverse fissure of the liver by the union of the ducts draining the right and left lobes. It runs inferiorly and posteriorly in the edge of the lesser omentum, lying anterior and to the right of the portal vein. The hepatic artery usually lies a short distance from its left margin.

The gall bladder is a thin-walled, musculo-membranous organ about 10 cm in length which lies in a fossa on the inferior surface of the right lobe of the liver. It is attached to the liver by loose connective tissue and is covered with peritoneum that is reflected from its sides onto the liver. The organ is divided into three parts: fundus, body, and neck. The wide end or fundus usually reaches the anterior border of the liver and may come in contact with the anterior abdominal wall. The normal gall bladder is never palpable, but if distended, it may be palpable in the angle between the right rectus muscle and the costal margin. The body lies in close relation to the duodenum, pyloric end of the stomach, and transverse colon. The neck is an S-shaped tube which empties into the cystic duct. Usually there is a saccululation at the neck, known as Hartmann's pouch.

The mucosa of the gall bladder consists of a single layer of columnar epithelium and may evaginate and project into the muscularis mucosae. These evaginations, which are found

in the normal gall bladder, are known as Rokitsansky-Aschoff sinuses.

The cystic duct runs posteriorly and medially to join the hepatic duct.

The common bile duct is the direct continuation of the hepatic duct after its junction with the cystic duct. It passes inferiorly in the edge of the lesser omentum, then behind the first part of the duodenum to run in a groove in the head of the pancreas and enter the second part of the duodenum at the ampulla of Vater, 2½ cm below the pylorus.

Blood Supply.—The common hepatic artery arises from the celiac axis, passes superiorly in the lesser omentum, and divides near the liver into the right and left hepatic arteries. The cystic artery usually arises from the right hepatic branch. It lies a short distance to the left of the cystic duct and supplies both the duct and the gall bladder. It should be emphasized that the course of the artery and its relation to the adjacent structures are subject to wide variation, and it is important therefore that all structures should be clearly visualized at operation.

Lymphatic Drainage.—Most of the lymphatic drainage converges on the cystic lymph node, which lies close to the junction of the cystic and common ducts, and from this node to the nodes in relation to the head of the pancreas and portal vein. Some of the lymphatics pass across the bare area of the gall bladder wall directly into the liver.

Nerve Supply.—The innervation of the gall bladder and bile ducts is through the splanchnic nerves and the right branch of the vagus nerve

EMBRYOLOGY

During the 4th week of fetal life a solid budlike outpouching forms on the ventral wall of the primitive foregut, from which develop the liver and the extrahepatic biliary system. This solid bud forms vacuoles which coalesce to form the gall bladder and ductal system. Any arrest of development at this stage may result in stricture or a congenital absence of the ducts or gall bladder. If, on the other hand, the bud splits in an abnormal manner, a double gall bladder, aberrant ducts, or diverticula of the gall bladder may result

directly into the duodenum. The liver secretes 500-1,000 ml. in 24 hours, and although the gall bladder holds but 30-50 ml, its concentrating power enables it to hold almost all the bile secreted during that period with the addition of some mucus which is secreted by the mucosa.

The ingestion of food stimulates the production in the duodenum and upper jejunum of the hormone *cholecystokinin* which produces a tonic contraction of the gall bladder. There is a reciprocal relaxation of the sphincter of Oddi, either in response to direct stimulation to acid chyme or to a nervous mechanism, allowing the concentrated gall bladder bile to enter the duodenum

The components of the bile are bile salts, bile pigments, and cholesterol. The bile salts,

Fig 300—Normal anatomy of the extrahepatic biliary system. Note how the intrapancreatic portion of the common duct can be occluded by disease in the head of the pancreas

PHYSIOLOGY

The chief functions of the gall bladder are to serve as a reservoir for liver bile, to control the pressure within the biliary tree, and to concentrate bile. The gall bladder also secretes mucus and at times cholesterol. The liver continually secretes a thin watery bile which does not contain mucin. The secretory pressure of the liver is 300-360 mm. of bile. If the intraductal pressure rises above that level, the liver ceases to secrete and jaundice occurs. Closure of the sphincter of Oddi at the terminal end of the common duct allows the pressure within the duct to rise sufficiently to force the bile into the gall bladder where it is concentrated 4-10 times. When the gall bladder is filled, the sphincter relaxes and the liver bile enters

sodium taurocholate and sodium glycocholate, are the most important constituents. They help to keep the cholesterol of the bile in solution, facilitate the digestive action of the pancreatic enzymes, particularly lipase, assist in the absorption of the products of fat cleavage, and stimulate the liver to produce additional bile. When bile salts fail to enter the intestines, 25-75% of ingested fat is lost in the feces.

DIAGNOSTIC PROCEDURES

Simple Roentgenography.—Most gallstones are not shown on plain roentgenograms, as only those with a high calcium content cast a definite positive shadow. Cholesterol and pigment stones are not radiopaque. Therefore, a negative roentgenogram is of little signifi-

cance in excluding disease of the gall bladder. Plain films of the abdomen may also demonstrate calcification of the gall bladder, gas in the biliary tree, a concentrated mixture of bile and calcium carbonate, or occasionally a soft-tissue shadow when carcinoma of the gall bladder is present.

Cholecystography.—The concentrating power of the gall bladder is of great clinical importance because the Graham-Cole test for cholecystitic disease is based on the assumption that a diseased gall bladder will not concen-

1. Failure to absorb the dye from the gastrointestinal tract, e.g., in vomiting or diarrhea
2. Failure of the liver to remove the dye from the blood stream and excrete it, e.g., in liver disease
3. Obstruction to the cystic duct
4. Premature emptying of the gall bladder before films are made, e.g., following ingestion of food prior to radiography
5. Presence of other shadows in the right upper quadrant which interfere with interpretation of the gall bladder shadow

Fig 301—Cholecystograms of normal gall bladder showing the contraction which occurs after a fatty meal

D, Thirty minutes after feeding

trate radiopaque dye that is excreted by the liver. In a relatively small number of patients several factors may influence the accuracy of the test

6. Failure of the gall bladder to concentrate the dye to an extent sufficient to produce a shadow
7. Failure of the patient to take the dye

The original contrast medium was tetraiodophenolphthalein, but this has been replaced by iodoaliphonic acid (Priodax) and iopanoic acid (Telepaque). These are preferably given by mouth. This test will give a positive diagnosis of cholelithiasis in a high percentage of cases. The accuracy of the test is considerably less in noncalculous disease of the gall bladder. Normally 12-14 hours are required following the ingestion of the dye for a satisfactory concentration to occur in the gall bladder.

Intravenous Cholangiography.—An intravenous dye having a very high iodine content (Cholografin) is a useful tool in demonstrating the various parts of the biliary tree. This is concentrated by the liver so that the hepatic and common bile ducts are visualized before the gall bladder is seen. It is particularly useful (1) after cholecystectomy, to demonstrate dilatation of the common duct, retained stones, or cystic duct remnant, (2) as a preoperative cholecystogram when oral cholecystography fails, (3) for children, and (4) for the investigation of tumors of the extrahepatic biliary system or pancreas which may partially occlude the common duct. However, the distal end of the common bile duct is often poorly visualized by this means, and the gall bladder shadow is not as dense as that visualized with Telepaque. The dye should not be used in the presence of jaundice, liver damage, or for those patients who have an iodine idiosyncrasy. If there is more than 30% retention using the Bromsulphalein test, the dye will not be excreted. In order to visualize the extrahepatic ductal system, several films must be taken within the first hour as the excretion is rapid.

Cholangiography.—A radiopaque solution, e.g., iodized oil, injected into the gall bladder or bile ducts, yields valuable information concerning the shape, content, and emptying of the main bile ducts. This procedure may be carried out during the operation where there is obstruction to the common duct or at a later date to ensure patency of the common duct prior to removal of the indwelling T tube.

Duodenal Drainage.—Duodenal intubation is of value as a diagnostic measure. A tube is passed into the duodenum, and gall bladder contraction is stimulated by the introduction of magnesium sulfate or olive oil. The pres-

ence of crystals of cholesterol and calcium bilirubinate in the aspirated material is confirmatory evidence of biliary tract disease.

PATHOGENESIS OF GALL BLADDER DISEASE

The experimental and clinical data on the bacteriology of the normal and inflamed gall bladder make untenable the common belief that bacterial infection is the usual cause of cholecystitis. While positive cultures have been obtained from the gall bladder wall, from the cystic lymph gland, and from the bile, there is no certain evidence that this phenomenon indicates more than secondary infection of the previously damaged viscus.

The existing evidence indicates that *cholecystitis* is nearly always due to chemical agents that are normally present in the body, namely, pancreatic juice and bile salts. While reflux of pancreatic juice can cause cholecystitis in man, proof is lacking that this is a common occurrence. Bile salts serve to keep cholesterol in solution, and hence if there is any significant lowering of the level of bile acids, cholesterol will be precipitated. Bile acids may pass through the mucosa of an inflamed gall bladder, thus decreasing the concentration and interfering with the bile salt-cholesterol ratio to cause precipitation of cholesterol. The cholesterol-bile salt ratio may also be increased in conditions which give a hypercholesteremia, such as in pregnancy, high fat diets, and in the premenstrual phase of the menstrual cycle. Overconcentration of the bile salts or other constituents of the bile, which may result from partial or complete obstruction of the cystic duct, exerts a damaging effect on the mucosa of the gall bladder. The obstruction may be due to a variety of factors, e.g., anomalies of the valves of Heister, of the cystic duct, adjacent adhesions, stone, etc. It has been shown that partial obstruction of the common duct will cause the formation of gallstones in the experimental animal, and there is some evidence that spasm or hypertrophy of the ampulla of Vater will cause enough resistance to the biliary flow to produce gallstones. It is also known that gall bladders will develop gallstones after choledochocenterostomy, presumably, in this case, due to bacterial action.

Fig 302—Variations in the position of the extrahepatic bile ducts. In operations in this area extra care must be taken to identify each structure prior to its ligation or section.

Fig 303—Variations in the position of right hepatic and cystic arteries. Ligation of the right hepatic artery may occur when anomalies are present. This accident, although no longer believed lethal, should never occur.

COMPLETE OBSTRUCTION

INCOMPLETE OBSTRUCTION

Plate 27.—Extrahepatic Biliary Obstruction.

Fig 301.—Calcified gall bladder.

Fig 305 —Cholecystograms A, Functioning gall bladder containing radiotranslucent (cholesterol) stones B, Multiple radiopaque calculi C, Functioning gall bladder with typical calcium ovalate gallstones D, Laminated gallstone.

The damaged mucosa is particularly liable to invasion by pathogenic bacteria, chiefly staphylococci, *Escherichia coli*, streptococci, and occasionally *Salmonella typhi*.

Chemical analysis reveals that gallstones are derived from the normal chemical constituents of the bile and are formed almost exclusively in the gall bladder. Cholesterol, calcium bilirubinate, and calcium carbonate are the principal stone-forming substances. A stone may be composed almost entirely of one of these compounds, e.g., pure cholesterol stone or a mixture of two or three.

Gallstones are likely to form when any one of the stone-forming constituents is in excess in the bile. Pigment stones composed of calcium bilirubinate are formed because of an increased excretion of bilirubin such as occurs in hemolytic jaundice. Cholesterol stones occur when there is a change in cholesterol metabolism. There is a hypercholesteremia in pregnancy which may account for the increased incidence of cholelithiasis in multiparous women. Stones also form when gall bladder function is so altered that the solvents (bile acids) are absorbed faster than the stone-forming constituents, and this leads to precipitation and crystallization. The pH of the bile may be of some importance, as an increased alkalinity tends to precipitate calcium carbonate. It seems probable, therefore, that no one mechanism can explain the occurrence of the different types of human gallstones.

Biliary tract disease is frequently associated with pancreatitis and appears to be more common in patients with diabetes mellitus.

DISEASES OF THE GALL BLADDER

Acute Cholecystitis

Etiology.—Acute cholecystitis is dependent in the great majority of cases upon an obstruction to the outlet of the gall bladder. In most instances this is due to a calculus impacted in the neck of the gall bladder or in the cystic duct. The obstruction blocks the outflow of bile and causes an accumulation of the normal secretions within the gall bladder. The resulting distention plus the edema at the site of obstruction impairs the arterial supply and the venous and lymphatic drainage of

the gall bladder. The resulting ischemia leads to necrosis and ulceration, which may go on to gangrene and perforation.

An overconcentration of bile salts is capable of injuring normal gall bladder tissue. This may be an added etiologic factor. Such an injured gall bladder wall is particularly liable to secondary bacterial invasion by *Streptococcus hemolyticus*.

Pathology.—The pathologic picture varies from mild inflammation to ischemia and gangrene of the gall bladder wall. In the typical case the wall of the gall bladder is red, thickened, and edematous. The serosal surface is congested and is often covered with fibrin. The mucosa is bright red. If the obstruction to the cystic duct is complete, the gall bladder is distended with what appears to be purulent fluid—the so-called *empyema of the gall bladder*. This fluid may be a sterile emulsion of cholesterol, mucus, and calcium carbonate, but true pus may be present.

Edema is responsible for most of the thickening of the wall. The inflammatory exudate is most marked in the outer layers and is characterized by a relatively small number of polymorphonuclear cells. A hemorrhagic exudate is a prominent feature. Not infrequently there is an associated pancreatitis.

A considerable number of acutely inflamed gall bladders yield positive bacterial cultures. The common organisms found are *E. coli*, streptococcus and staphylococcus, and gram-negative bacilli.

Clinical Picture.—There is frequently a history suggestive of previous gall bladder disease. The onset of symptoms in the acute attack is usually sudden, with pain in the right hypochondrium, reaching its peak in 24 hours. The pain may radiate to the right scapular region and to the right shoulder. Nausea and vomiting are common. Tenderness over the gall bladder is constant and is associated with muscle spasm. The gall bladder is usually palpable despite this muscle resistance. Fever is common and is accompanied by tachycardia and leukocytosis. Jaundice may occur occasionally if there is an associated hepatitis, cholangitis, or common duct obstruction due to stone, inflammatory edema, or pressure on the common duct from swelling of Hartmann's pouch.

The acute symptoms usually subside in 2-3 days, but tenderness, rigidity, and a palpable mass are likely to persist for a considerable period. However, the improvement in the clinical picture is often misleading and cannot be directly correlated with a corresponding improvement in the disease process. The condition may go on to abscess formation and even gangrene.

Differential Diagnosis.—Acute cholecystitis must be differentiated from perforated or penetrating peptic ulcer, acute appendicitis, acute pancreatitis, and coronary thrombosis.

With perforated peptic ulcer, there is often a previous history of epigastric pain, which was relieved by food and alkalis. The tenderness is acute and the rigidity is boardlike; both are more generalized, and there is usually a loss of liver dullness; an x-ray of the abdomen may show air in the peritoneal cavity. The differentiation from acute pancreatitis is difficult. The pain and tenderness in pancreatitis are more diffuse, tend to radiate to the left lumbar region, and the vomiting is more severe. An elevated serum amylase is of diagnostic significance.

In acute appendicitis the location of maximum pain and tenderness is in the right iliac fossa or loin and is associated with rectal tenderness. In the high-lying retrocecal appendix the differentiation may be impossible. In coronary thrombosis the pain frequently radiates down the left arm. There is hypotension with typical electrocardiographic changes. However, similar changes in the electrocardiogram may result from an attack of acute cholecystitis.

Treatment.—Operative treatment is indicated for all cases of acute cholecystitis, although there is wide divergence of opinion as to the optimum time for operation. If the patient is seen early, the gall bladder should be removed. This eliminates the source of infection and risk of perforation, gives a smoother convalescence, avoids the need for future operation, and can be performed without difficulty. If the patient is seen late when the symptoms are subsiding, conservative measures are preferable as they carry the least risk. Operation should not be delayed if there is increased pain, tenderness, and rigidity, and

if the pulse rate, temperature, and leukocyte count do not quickly return to normal.

Cholecystostomy is indicated (1) when the patient's general condition is so serious that only the simplest and quickest operation can be considered, and (2) in patients with edema or adhesions about the common duct of such a nature that a cholecystectomy is particularly difficult.

Adequate antibiotic therapy should be used in all cases. Dehydration is not uncommon, and this necessitates adequate fluid prior to operation. The glycogen and protein reserves of the liver should be replenished by the parenteral administration of the substances.

If the early treatment has been of a conservative nature, cholecystectomy should be performed at a later date when the acute process has completely subsided.

Chronic Cholecystitis and Cholelithiasis

Etiology.—In the section on pathogenesis of gall bladder disease it has been pointed out that cholecystitis is the result of chemical irritation, metabolic disturbance, or enzyme action. Infection, if present, is probably a secondary factor. Occasionally chronic cholecystitis may manifest itself after an acute attack.

Pathology.—The healthy gall bladder is translucent, and one of the earliest signs of pathologic change is the development of opacity. In the later stages of cholecystitis, the wall of the gall bladder becomes thickened and opaque. Inflammatory adhesions frequently develop between the gall bladder and adjacent viscera. The microscopic appearance may be one of fibrosis or chronic cellular inflammatory changes. Gallstones cause or largely contribute to the pathologic change in the gall bladder by predisposing to biliary stasis, by trauma to the mucosa, and by cystic duct obstruction.

Hydrops of the gall bladder results if the cystic duct becomes obstructed in the absence of acute inflammation. The bile pigments and salts are gradually absorbed and are replaced by a watery secretion, white bile, from the mucosal surface. The gall bladder may become very distended and may contain as much as 500 ml. of fluid.

Cholesterosis of the gall bladder is the result of a local or general change in cholesterol metabolism, characterized by the deposition of large amounts of cholesterol or cholesterol esters in the mucous membrane. The resulting small yellow specks, like strawberry seeds, have given the condition the name of "strawberry gall bladder." Stones may be present and are frequently of the pure cholesterol type. The symptoms here are similar to those in other forms of gall bladder disease.

of gallstones appears to increase with age, many patients with stones apparently are asymptomatic or exhibit only minor symptoms.

The symptoms of gall bladder disease are those of gastrointestinal upset and pain. The gastrointestinal symptoms are primarily due to pylorospasm and spasm of the sphincter of Oddi with resultant delay in the emptying of the stomach and biliary tract. This results in epigastric fullness and postprandial distress which is relieved by belching. Many types of

Fig. 306--Cholecystograms showing a functioning gall bladder with gallstones. Note that the gallstones are not visible in the supine film. Contraction of the gall bladder following a fatty meal pushes the gallstones toward the cystic duct. It can be readily seen how one or several of the gallstones can enter the biliary ductal system, causing obstruction.

A. Supine before fat
B. Upright before fat

C. Fifteen minutes after fat
D. Thirty minutes after fat

Clinical Picture.—Cholecystitis and cholelithiasis most commonly occur in the obese middle-aged female but are also found in males and even in children. As the incidence

of food may cause distress, but it is especially true for those of a fatty nature.

The pain may be mild and limited to a dull right upper quadrant ache or severe with radi-

tion to the right scapular region, the right shoulder tip, and the right flank. Most patients with chronic disease of the gall bladder will have one or more attacks of biliary colic during the course of the disease. In its typical form this is pathognomonic of biliary tract disorders. This pain is due to distention of the gall bladder and to peritoneal irritation. It begins suddenly with the usual radiation, is steady, and slowly progresses in intensity. There is usually a history of a mild epigastric ache which precedes the pain due to distention of the gall bladder, and the pain is only felt in the gall bladder area when the distended viscus comes in contact with the parietal peritoneum. The attack is frequently accompanied by nausea and vomiting.

with radiologic confirmation by cholecystography. Tenderness over the gall bladder may be present. This tenderness may be increased if the patient is made to inspire during palpation (Murphy's sign). Fever and leukocytosis are uncommon.

Differential Diagnosis.—Chronic gall bladder disease must be differentiated from peptic ulcer, chronic pancreatitis, disease of the upper urinary tract, recurrent appendicitis, and coronary artery disease.

Treatment.—If it can be demonstrated that chronic gall bladder disease with or without stones exists, cholecystectomy is the treatment of choice. If, however, the evidence is equivocal, the surgeon should hesitate to operate. Symptoms such as dyspepsia and flatulence

A, Supine B, Upright

Occasionally there is a definite relationship between angina pectoris and gall bladder disease. In such cases cholecystectomy will cure the symptoms of gall bladder disease, the simulated anginal pain, and will cause an improvement in the electrocardiograph.

Physical examination reveals few signs, and the diagnosis is made on a careful history

are prone to persist after operation unless the pathologic changes in the gall bladder are definite. The operation of cholecystostomy is rarely if ever indicated.

Silent Gallstones

The increased use of radiography as an adjunct to routine physical examination has

resulted in the demonstration of gallstones in patients who did not complain of symptoms referable to the biliary tract. These patients are often considered to have so-called silent gallstones in a functioning gall bladder. However, we feel that a careful interrogation will elicit a history of gall bladder disease.

Many observers feel that nonoperative treatment, coupled with careful follow-up and repeated cholecystograms, is the treatment of choice. However, the risk of developing acute cholecystitis, acute pancreatitis, common duct stone, and conceivably carcinoma of the gall bladder is such that elective cholecystectomy should be advised in all patients of this type whose general physical condition does not increase the hazard of the operation.

spontaneous biliary fistulas follow an attack of acute cholecystitis. The gall bladder becomes adherent to the anterior abdominal wall, and the stoma develops by erosion through the muscle and skin. Postoperative external fistulas follow cholecystostomy, cholecystectomy, or operations on the common duct.

Clinical Picture.—In internal fistulas the symptoms are those of biliary tract disease. The stone may become impacted in the duodenum or terminal ileum and cause acute intestinal obstruction. Such a cause should be suspected in intestinal obstruction if air is seen in the biliary tract or a shadow of a stone in the scout film. Fever and jaundice result from an associated cholangitis. Hematemesis and melena sometimes occur.

Fig 308—A plain film of the abdomen showing air in the gall bladder, duodenum, and common bile duct due to a fistula between the gall bladder and the duodenum.

Biliary Fistula

Etiology.—Biliary fistulas are uncommon. There are three principal types

- 1 Spontaneous internal
- 2 Spontaneous external
- 3 Postoperative external

Spontaneous fistulas, either internal or external, are associated in the majority of cases with gallstones and result from the erosion of a stone through the wall of the gall bladder or common duct, generally into the duodenum, stomach, or colon. They may also follow penetrating peptic ulcer or carcinoma of the gall bladder, stomach, or pancreas. Most external

Spontaneous external fistulas occur near the umbilicus or in the right upper quadrant of the abdomen. The biliary tract should be investigated carefully in all patients who develop abscesses or sinuses in these areas. X-ray findings of air in the bile ducts or of barium in the biliary tract following a barium meal is strong evidence of biliary fistula.

Treatment.—In spontaneous fistulas and in those fistulas which follow cholecystostomy, the treatment is cholecystectomy, excision of the fistulous tract, and closure of the opening in the intestine. If intestinal obstruction is present, the offending stone should be removed. In fistulas following cholecystectomy

and operations on the common duct, the tract should be excised, any biliary obstruction relieved, and a T tube placed in the common duct.

Traumatic Rupture

Rupture of the gall bladder or ducts may occur following penetrating wounds or trauma to the abdominal wall. Adjacent abdominal viscera are frequently involved.

The clinical picture is one of initial shock, followed by a period of improvement. There is a dull pain in the upper abdomen, and within a short time the abdomen slowly distends with fluid. Jaundice due to absorption of bile from the peritoneal cavity comes on after a few days.

Treatment is usually cholecystectomy. If the tear is in the fundus, it may be sutured without drainage or a cholecystostomy may be performed. If the bile ducts are injured, they should be repaired over an indwelling T tube. Any bile found in the abdominal cavity should be sucked and even washed out. Chemotherapy should be instituted.

Bile Peritonitis

Sterile bile in the peritoneal cavity causes a chemical peritonitis which pursues a relatively benign course. However, as most cases follow operations on a diseased gall bladder, the bile is usually infected and the peritonitis while mild at first becomes progressively worse.

Etiology.—Bile peritonitis occurs following either spontaneous or traumatic rupture of the gall bladder or bile ducts or after an operative procedure.

Treatment.—Early operation is indicated. The bile in the peritoneal cavity should be aspirated, tears repaired, and a drain placed alongside the common duct so that any future leak may be aspirated. Most cases of bile peritonitis can be avoided by meticulous surgery, and drains should always be placed down to the operative site so that any bile leakage will drain to the exterior.

Tumors of the Gall Bladder

Benign

Benign tumors of the gall bladder, adenomas, lipoid polyps, and papillomas, are usu-

ally asymptomatic. True papillomas are extremely rare, and most recorded papillomas are merely polypoid swellings of the mucosa due to cholecystitis glandularis proliferans. The distinction between the true tumors and the pseudopolyps is almost impossible and of little practical importance. Both should be removed, as the true papilloma is precancerous and the pseudopolyp is an indication of chronic gall bladder disease.

Malignant

Carcinoma is, for all practical purposes, the only malignant tumor of the gall bladder. Sarcoma, melanoma, and endothelioma occur but are extremely rare.

Incidence.—Primary carcinoma of the gall bladder is an uncommon tumor of the digestive tract. It occurs predominantly in females in a ratio of 4:1. This ratio parallels the incidence of cholelithiasis in the two sexes.

Etiology.—The presence of papillomas and calculi appears to be related to the development of carcinoma. While papillomas have the capacity to undergo malignant change, this transformation rarely occurs in the gall bladder. The relationship of cholelithiasis to a carcinoma of the gall bladder is interesting and probably important, as the great majority of cases show the presence of stones prior to the development of the neoplasm.

Pathology.—Carcinoma of the gall bladder is divided into two main groups: adenocarcinoma and squamous cell carcinoma. The majority of cases are varieties of adenocarcinoma, papillary, mucoid, and scirrhous. The wall of the gall bladder is thick, hard, and contracted, and at operation the condition may be mistaken for chronic cholecystitis. The tumor metastasizes early with direct spread to the liver, to adjacent organs, or along the bile passages. Distant spread may occur to lungs, bones, and other systemic organs.

Clinical Picture.—The preoperative diagnosis of carcinoma of the gall bladder is seldom made. The symptoms are usually those of long-standing biliary tract disease, although with the onset of malignancy they become more severe. Pain is a prominent feature. Occasionally the onset is insidious, and the diag-

nosis is made only when metastases develop. Jaundice may occur from hepatic involvement or from blockage of the ducts. A palpable mass in the gall bladder region is a late sign. Acute perforation may occasionally occur.

Differential Diagnosis.—It is seldom possible to differentiate carcinoma of the gall bladder from chronic cholecystitis. Cholecystography is of little help; it merely demonstrates gall bladder dysfunction of varying degree. The advanced case must be differentiated from other neoplasms in the upper abdomen.

Treatment.—Cholecystectomy offers the only hope of cure. This procedure is frequently impossible because of the extension of the disease. The removal of the calculous gall bladder may be of value in the prevention of malignant change.

DISEASES OF THE BILE DUCTS

The clinical manifestations of biliary duct disease are the result of either (1) obstruction, (2) infection, or (3) functional motor disturbances.

OBSTRUCTION

The cause of the obstruction may be (a) in the wall (congenital stricture, choledochus cyst, acquired stricture, inflammatory edema) (see also Chapter 30), (b) in the lumen (stone, tumor), or (c) outside the duct (chronic pancreatitis, carcinoma of the pancreas).

Congenital Anomalies

Congenital Cystic Dilatation of the Common Duct (Choledochus Cyst)

Choledochus cyst is a rare anomaly characterized by a localized dilatation of the common duct and probably due to a congenital weakness of the wall, to which has been added an obstructive factor, such as stenosis, angulation, inflammation, or achalasia.

Pathology.—The cyst is retroperitoneal and arises from the supraduodenal portion of the common duct. Its wall consists of dense fibrous tissue without a lining epithelium. The cyst varies greatly in size, may have a capacity of several liters, and contains bile-stained fluid.

Clinical Picture.—Choledochus cyst occurs predominantly in the female. It rarely produces symptoms before the age of 6 months. The clinical features are intermittent jaundice, colicky right upper abdominal pain, and a cystic swelling in the right hypochondrium. Clay-colored stools occur.

Treatment.—The treatment of choice is anastomosis between the cyst and duodenum. If this is not feasible, a cholecystoduodenostomy may be performed.

Congenital Atresia of the Bile Ducts

The obliterative process may involve the bile channels within the liver, the hepatic ducts, the cystic duct, the common duct, or the gall bladder. The involved portions may be completely absent or may be represented by cords of fibrous tissue. There is an associated widespread biliary cirrhosis.

Fig. 309—Degrees and locations of congenital atresia of the extrahepatic bile ducts.

Clinical Picture.—Jaundice is present from birth and progressively deepens for the duration of life. As the obstruction is complete, the stools are clay colored from birth. The abdomen may appear prominent due to enlargement of the liver and spleen. Ascites is present in late cases. In the untreated patient, death inevitably occurs but only after many months.

Differential Diagnosis.—The condition must be differentiated from other causes of jaundice in infancy, principally icterus neonatorum and erythroblastosis fetalis.

Treatment.—The treatment consists of an anastomosis between the proximal patent portion of the biliary system and the duodenum, although in many cases this is not possible because of the type or extent of the atresia. As in all jaundiced patients, care must be taken preoperatively to control the bleeding tendency with adequate amounts of vitamin K and transfused whole blood.

Impassated Bile or Mucus

These may plug the biliary ducts and give a picture that is indistinguishable from congenital atresia of the bile ducts.

Treatment.—Laparotomy with irrigation of the duct system will usually dislodge the obstructing plug and cure the condition.

Acquired Anomalies

Cholelithiasis

Approximately 15% of patients who undergo laparotomy for cholelithiasis have one or more stones in the common duct. These stones usually originate in a diseased gall bladder but occasionally develop within the ductal system. They may remain in the ducts or pass through the ampulla of Vater without producing symptoms. However, if they become impacted, symptoms of biliary tract obstruction occur.

Pathology.—Obstructing stones are usually single, but once obstruction occurs, secondary stones and gravel accumulate. The degree of dilatation of the ductal system depends upon the duration and completeness of the obstruction and whether it is intermittent or continuous. Mucosal ulceration occurs at the site of an impacted stone and may result in stricture or, more rarely, perforation. Inflammatory changes occur in the duct walls which may go on to thickening and fibrosis.

The effects on the liver depend upon the duration of the obstruction. If this is of long standing, varying degrees of hepatocellular damage occur, leading to derangement of liver function.

Clinical Picture.—The history of intermittent, colicky, sometimes severe, right upper quadrant pain, intermittent fever, and fluctuating jaundice is characteristic of biliary duct stone. The ball valve action of the stone is responsible for the intermittent character of the symptoms. Occasionally the obstruction is complete, leading to a steadily deepening jaundice. The pain is more severe than that associated with acute cholecystitis and frequently radiates through to the right scapular region and the right shoulder. It may radiate to the left hypochondrium and epigastrium. If the obstruction is complete, the pain is continuous and steady. The fever characteristically is of the intermittent type (Charcot's intermittent biliary fever), accompanies an exacerbation of the pain, and is commonly associated with a chill. There may be an associated *E. coli* septicemia. The jaundice varies in degree and usually fluctuates, although it may be steadily progressive if the stone is firmly impacted. The urine contains large amounts of urobilinogen and bile pigments, while the stool is characteristically pale. The biochemical findings are typical of obstructive jaundice, namely, an elevation of the serum bilirubin, an elevated alkaline phosphatase, and normal flocculation tests.

A plain x-ray film of the abdomen may show the presence of stones. A cholecystogram cannot be successfully carried out in the presence of jaundice.

If the stone does not cause obstruction, the symptoms will be simply those of the associated gall bladder disease without jaundice.

Differential Diagnosis.—The disease must be differentiated from the following.

- 1 Acute cholecystitis, acute pancreatitis, perforated peptic ulcer, renal colic, and coronary thrombosis.

- 2 Other causes of obstructive jaundice such as carcinoma of the head of the pancreas and chronic pancreatitis.

- 3 Intrahepatic jaundice.

Treatment.—While antispasmodics, e.g., atropine, may bring relief in the acute attack, the treatment of ductal stone is surgical. The preoperative preparation is of prime importance. The liver must be protected by a diet high in protein and carbohydrate. The bleed-

Fig 310—Intravenous cholangiograms
 A, Normal ductal system, postcholecystectomy
 B, Common duct stone
 C, Cystic duct remnant

ing tendency must be counteracted by parenteral vitamin K and whole blood transfusions. The biliary tract must be decompressed in order to relieve the jaundice and the back pressure on the liver. When the patient's condition permits, the ducts must be explored thoroughly and all stones and debris removed. The ampulla of Vater should be dilated carefully to ensure free passage of bile into the duodenum. The gall bladder, if present, should then be removed and the common duct closed over an indwelling T tube.

Fig 311—Cholangiogram through an indwelling common duct T tube, showing the hepatic ducts, the common hepatic duct, and the common bile duct. The distal end of the common bile duct is blocked by a calculus.

Prior to the removal of the T tube a cholangiogram must be made to ensure that no stones remain in the common duct and that the ampulla of Vater is patent.

Stricture

Etiology.—In the majority of cases, acquired stricture of the common duct is the result of injury during operations on the biliary tract. However, it is occasionally associated with ulceration of the duct due to gallstones, with cholangitis and periductal abscess, with the spread of infection from the pancreas, and with tumors.

Clinical Picture.—If jaundice follows immediately after an operation, the common bile duct has been ligated or there is a residual stone. If, however, an external biliary fistula occurs, one may assume that the duct has been partially or completely divided. If the duct has been only partially divided, late stricture will occur with subsequent jaundice and cholangitis.

Differential Diagnosis.—Postoperative stricture must be differentiated from a retained common duct stone. This is frequently impossible without operation. However, cholangiography is of value if a T tube remains in the common duct.

Treatment.—Injury to the common duct can be prevented. Anomalies of the ducts and vessels must be recognized, and all structures must be carefully visualized before any ligation or division is carried out. The treatment of acquired stricture is a most difficult surgical procedure. An effort must be made to reconstruct the ducts and re-establish continuity, and a mucosa-to-mucosa junction should be obtained whenever possible in order to prevent the occurrence of another stricture. If the gall bladder is present and functioning and the stricture is distal to the entrance of the cystic duct, an anastomosis between the gall bladder and the intestinal tract may be satisfactory.

Tumors of the Bile Ducts

Tumors of the extrahepatic biliary tract are uncommon. They may arise anywhere in the ducts, but the commonest site is the ampulla of Vater.

Pathology.—Benign growths are exceedingly rare. Carcinoma is the important tumor. It is usually a diffusely infiltrating adenocarcinoma. In contrast to neoplasm of the gall bladder, these tumors of the ducts are rarely associated with stone.

Clinical Picture.—The onset is insidious with jaundice as the first symptom. The jaundice is obstructive in type. Dull upper abdominal pain resulting from raised intraductal pressure may accompany the icterus. The growth may ulcerate and produce gross or microscopic blood in the stool and a marked secondary anemia. The symptoms tend to be steadily

progressive in contrast to those associated with stone in the common duct.

Physical findings aside from the jaundice are not remarkable. However, if the tumor lies in the lower end of the common duct distal to the cystic duct, the gall bladder will become distended and palpable.

Differential Diagnosis.—Carcinoma of the head of the pancreas, chronic pancreatitis with obstruction, and common duct stone give a similar picture.

Treatment.—In the case of a malignant tumor, a resection of the duodenum, head of the pancreas, and the involved portion of the duct should be carried out. Local resection may be done for benign growths and malignant tumors that are confined to the ampulla. In the majority of cases local spread makes these procedures impossible, and a palliative operation, such as a cholecystojejunostomy, must be done to relieve the jaundice.

INFECTION

Cholangitis

Etiology.—Cholangitis is an inflammatory process which involves the walls of the biliary passages and is usually associated with some obstruction to the free flow of bile. The obstruction is usually the result of stone or stricture of the common duct which predisposes to bacterial invasion. However, it may result from regurgitation of intestinal contents into the common duct.

Pathology.—The degree of cholangitis varies from a simple catarrhal inflammation to frank suppuration with resultant fibrosis and thickening. The inflammatory process may spread through the wall to involve the periductal tissues or extend upward into the tributaries of the bile ducts to involve the liver parenchyma. It may extend until all liver ducts are filled with pus.

Clinical Picture.—Acute suppurative cholangitis presents a picture of repeated episodes of chills, fever, and deepening jaundice. The liver is usually enlarged and tender. The more chronic forms do not present a definite clinical picture, although they tend to flare up in the presence of obstruction, leading to further damage to the liver and ductal system.

Treatment.—The treatment is mainly prophylactic, with relief of biliary tract obstruction. In the acute suppurative phase, the treatment is drainage of the common duct and adequate doses of antibiotics.

FUNCTIONAL MOTOR DISTURBANCES

Biliary Dyskinesia

Biliary dyskinesia is an obstruction to the flow of bile without jaundice, due to a neuromuscular dysfunction of the sphincter of Oddi. Such a disturbance is rare in the absence of other biliary tract symptoms, in whom no evidence of organic disease can be demonstrated, the possibility of dyskinesia should be kept in mind.

Treatment.—The encouragement of bile flow by diet, bile salts, and antispasmodics may bring relief. Dilatation or cutting of the sphincter of Oddi has been reported to be of value.

Postcholecystectomy Syndrome

The symptoms of biliary tract disease may persist or recur following cholecystectomy or choledochostomy. Most commonly this occurs following removal of a noncalculous gall bladder and is found in almost inverse proportion to the degree of pathologic change in the gall bladder wall. Symptoms, however, can recur after cholecystectomy in properly selected cases and are usually due to residual disease. In such cases retained cystic or common duct stone, infection in the cystic duct stump, and neuromas of the periductal nerve plexus are probable etiologic factors. Unfortunately, only too frequently, abdominal exploration reveals no abnormality.

Treatment.—Elimination of the residual organic disease by removal of stones, amputation of the remains of the cystic duct, periductal stripping of the nerve plexus may give relief.

OPERATIVE PROCEDURES

Cholecystectomy

The indications for cholecystectomy are limited and include the following:

1. In acute cholecystitis in the poor operative risk patient or when cholecystectomy presents unusual technical difficulties

2. In certain cases of acute necrosing pancreatitis

3. As a first-stage procedure in certain cases of jaundice due to carcinoma of the head of the pancreas or to chronic pancreatitis

Anesthesia.—Either local, regional, or general anesthesia may be employed

Operation.—A high paramedian or a right subcostal incision is used. Care must be taken

to avoid spilling infected bile into the peritoneal cavity, and the area should be packed off before proceeding. When the gall bladder is exposed, its contents are aspirated with a wide bore needle and syringe or with a trochar and suction. The fundus of the gall bladder should be supported with two Allis forceps or sutures and an incision made of sufficient length to permit entrance of the special scoops which are used to remove the stones. Care should be taken to remove all the stones present and ensure patency of the cystic duct.

Fig 312—Technique of cholecystectomy and choledochostomy

A good-sized rubber tube is passed into the gall bladder and securely anchored. The opening of the gall bladder is closed about the tube, which is then brought out through the abdominal incision and connected to a receptacle.

Complications.—Approximately 40% of the patients having a cholecystostomy for gall bladder disease will have recurrent symptoms which require future operation

Cholecystectomy

Indications for cholecystectomy include the following

- 1 Cholecystitis and cholelithiasis
- 2 Traumatic rupture of the gall bladder
- 3 Tumors of the gall bladder
- 4 Internal or external biliary fistulas

Anesthesia.—Adequate relaxation is a prerequisite to good biliary surgery. Either spinal or inhalation anesthesia is used.

Operation.—The commonly used incisions are right paramedian or right subcostal.

The gall bladder may be removed (1) by starting at the fundus and dissecting down to the cystic artery and cystic duct or (2) by preliminary ligation of the artery and duct with subsequent removal of the gall bladder. The latter procedure is usually preferable, and the former should be reserved for those cases where a large stone or adhesions tend to make clear visualization of the duct system difficult.

The fundus of the gall bladder is grasped with a pair of nontoothed artery forceps and drawn up over the edge of the liver. A second forceps is placed on the gall bladder in the region of Hartmann's pouch. When moderate traction is exerted on these forceps, the cystic duct is placed on the stretch. A small incision is made in the peritoneum over the neck of the gall bladder, and by careful dissection the whole length of the cystic duct is exposed. The next step is to display the cystic artery which lies above and slightly posterior to the duct. The various anomalies must be kept in mind, and great care must be taken to display and identify each structure before ligation or division.

When the dissection is complete, the artery is divided between ligatures. The cystic duct

is then divided between forceps $\frac{1}{8}$ " from the common duct and doubly ligated. Care must be taken to avoid inclusion of the common duct in the ligature. The gall bladder is then removed from the liver bed, preserving sufficient peritoneum to cover the raw area on the liver. Soft rubber drains should always be placed in the gall bladder fossa and should not be removed for several days.

Choledochostomy

The indications for choledochostomy include the following:

1. The presence of jaundice or a previous history of icterus
2. Dilated or thickened common duct
3. Palpable stones in the common duct
4. Small stones in the gall bladder with a patent cystic duct
5. In some cases of acute pancreatitis and in those cases of chronic pancreatitis causing common duct obstruction

Operation.—The cystic and common duct are placed on the stretch by traction on the gall bladder. The common duct is isolated, aspirated, and the character of the bile noted. Two stay sutures of fine silk are placed on its anterior surface, and a small incision is made in the duct parallel to its long axis between the two stay sutures. The duct should be irrigated to remove all sand and small stones. A probe is then passed down the duct into the duodenum to ascertain that the ampulla is patent. The ampulla should be dilated with graduated probes. The proximal portions of the ducts must be explored and irrigated to obviate leaving small stones. A T tube is then inserted into the common duct, sutured in place, and the long limb is brought out through the incision and securely fixed to the abdominal wall. The operation is completed by cholecystectomy. Occasionally the stone is so impacted in the ampulla that the duodenum must be opened and the ampulla of Vater sectioned to release it.

Chapter 21

Pancreas

Harry S. Dolan, M.D., and James F. Hopkirk, M.D.

ANATOMY

The pancreas is a retroperitoneal gland which lies in the upper part of the abdomen at the level of the bodies of the 1st and 2nd lumbar vertebrae. It extends from the duodenum on the right to the spleen on the left and is divided into four parts: head, neck, body, and tail. The head lies in the concavity of the duodenum, and its posterior relations are the inferior vena cava and tributaries of the portal vein. The posterior relations of the body are the aorta, superior mesenteric artery, left renal vein, left adrenal gland, and left kidney. The anterior relations of the entire gland are the stomach and the lesser peritoneal sac. The transverse colon is an inferior relation of the pancreas.

The main pancreatic duct (of Wirsung) traverses the complete length of the gland from the tail to the head and usually opens into the duodenum through the ampulla of Vater. In 70% of cases it joins the common bile duct at the ampulla. Occasionally the pancreatic duct joins the common bile duct some distance from the duodenum, or the two ducts open separately into the duodenum. The accessory pancreatic duct (Santorini) enters into the duodenum 2 cm. above the ampulla and rarely joins the common duct.

The blood supply of the pancreas is derived from the superior and inferior pancreaticoduodenal arteries, the splenic artery, and branches from the hepatic artery. The lym-

phatic distribution is rich and drains into the pancreaticoduodenal, preaortic, and celiac nodes. There is also some lymphatic connection between the pancreas, gall bladder, stomach, and spleen.

The nerve supply of the pancreas is via the vagus and sympathetic systems. The vagus is the secretory nerve of the pancreas and controls one phase of its external secretion. The sympathetic nerves (splanchnics) carry the afferent pain fibers.

HISTOLOGY

There are two different types of cells: i.e., those concerned with the external secretion which are very numerous and are arranged in acini that empty into branches of the ductal system, and those concerned with the internal secretion which are relatively few in number and are arranged in clusters or islands known as the islets of Langerhans. These islets form but a small part of the pancreas as a whole and are chiefly found in the tail.

EMBRYOLOGY

The pancreas develops as two endodermal evaginations, dorsal and ventral, from that part of the primitive gut which goes to form the duodenum. The dorsal evagination makes up the body, tail, part of the head of the pancreas, and the accessory pancreatic duct. The remainder of the pancreatic head and the main pancreatic duct arise from the ventral evagination.

The common bile duct originates from the ventral evagination which accounts for the close association of this duct with the main pancreatic duct

PHYSIOLOGY

The pancreas secretes 1,000-2,000 ml./24 hours. It is alkaline in reaction with a pH of 8.4-8.6. The chief salts are sodium, potassium, calcium, and magnesium.

The pancreas has two main functions:

1. The manufacture of an internal secretion (insulin), which is one of the main controlling factors in carbohydrate metabolism.

2. The manufacture of an external secretion containing a number of digestive ferments,

the chief of which are lipase, trypsin, amylase, and, in addition, maltase, lactase, and rennin.

The insulin controls the level of the blood sugar in the body. The pancreas and the liver are the main means of control of the mobilization and utilization of glucose, and the formation of glycogen from carbohydrate sources. Secretion of insulin occurs after taking food, particularly that of a carbohydrate nature.

Removal of the pancreas results in diabetes, which is, however, less severe in its manifestations than true primary diabetes. An increase in the secretion of insulin results in hyperinsulinism which is found in certain diseases of the pancreas, such as adenoma or hyperplasia of the islet tissue.

Fig 313—The normal anatomy of the region of the pancreas. Note the intraglandular portion of the common bile duct and how easily it may be occluded by disease in the pancreatic head to cause jaundice. Note, too, the variations in the common bile and pancreatic duct junctions. From an anatomic viewpoint the common channel theory of the etiology of acute pancreatitis is tenable.

The external secretion is stimulated by the vagus nerve, causing a secretion of a thick viscid juice which is rich in ferments, and by a hormone elaborated in the duodenum and upper jejunum, secretin, which passes via the blood stream to the pancreas, where it causes a copious watery secretion of low enzyme content, containing chiefly inorganic alkaline salts.

Secretin is produced by the action of hydrochloric acid and certain foodstuffs, chiefly those of a fatty nature. It is probable that the hormone causes its response through the mediation of the vagus nerve. In addition to its effect on the flow of pancreatic juice, it also increases the flow of bile and duodenal juice.

The action of the sympathetic system on pancreatic secretion is not as yet entirely defined, as either sympathetic stimulation or section will at times cause an increase in secretory flow.

A knowledge of the control of the internal and external secretions of the pancreas is most important when planning the therapy of patients with either acute or chronic pancreatic disease.

DEVELOPMENTAL ANOMALIES

The chief abnormalities encountered are variations of the pancreatic ductal systems and ectopic or aberrant pancreatic tissue which is found in the mesentery, omentum, gall bladder, biliary system, liver, and mediastinum.

Aberrant Pancreatic Tissue

Isolated masses of pancreatic tissue, which are completely separate from the main gland, occur in various parts of the gastrointestinal tract. Most commonly these are found in the region of the stomach, duodenum, and upper jejunum, and are located in the submucosa.

Gross Appearance.—Aberrant tissue is found as small nodules which measure 1-3 cm in diameter and have the color and appearance of normal pancreatic tissue.

Microscopically these have the characteristics of normal pancreatic tissue. They occasionally give rise to symptoms, the nature of which chiefly depends on their site, size, and physiologic activity. For example, when pancreatic tissue is found in the pyloric region of the

stomach, the symptoms may mimic duodenal ulcer or new growth.

Intussusception of the small bowel may result from the presence of aberrant pancreatic tissue in the bowel wall. Hyperinsulinism may be caused by aberrant tissue.

Treatment.—The treatment is local excision, and a careful search must be made in all the possible sites. Occasionally, resection of the bowel or stomach is necessary.

Annular Pancreas

This is a rare abnormality in which the head of the pancreas encircles the duodenum, causing duodenal obstruction of varying degree. The symptoms are those of chronic pyloric obstruction with gastric distention, nausea, and vomiting. The ideal treatment is division and resection of part of the head of the pancreas. In children this has resulted in fistula formation, and therefore duodenojejunostomy has become the accepted treatment. In some cases a gastroenterostomy or partial gastrectomy may be required.

LABORATORY AIDS IN DIAGNOSIS
